## ABSTRACT

The proceedings of the 24th annual meeting of the Psychology of Mathematics Education North American Chapter (PME-NA) contains research reports, plenaries, and poster presentations. Papers include: (1) "What Do We Believe about Teacher Learning and How Can We Learn With and From Our Beliefs?" (Deborah Loewenberg Ball); (2) "Toward Evidence for Instructional Design Principles: Examples from Cognitive Tutor Math 6" (Kenneth R. Koedinger); (3) "Achieving Equity and Improving Teaching in Mathematics Education through Teacher Education and Professional Development" (Laurie E. Hart, and Martha Alleksaht-Snyder); (4) "Exploration of Patterns and Recursive Functions" (Lourdes Guerrero and Antonio Rivera); (5) "Exploring the Role of Metonymy in Mathematical Understanding and Reasoning: The Concept of Derivative as an Example" (Michelle J. Zandieh); (6) "A Content Analysis of Exit Level Mathematics on the Texas Assessment of Academic Skills: Addressing the Issue of Instructional Decision-Making in Texas" (Jere Confrey and David Carrejo); (7) "Entailments of the Professed-Attributed Dichotomy for Research on Teachers' Beliefs and Practices" (Natasha M. Speer); (8) "Writing Conjectures in Geometrical Activities with Cabri-Geometre" (Ernesto A. Sanchez Sanchez and Miguel Mercado Martinez); (9) "Student-to-Student Questioning in the Development of Mathematical Understanding: Six High School Students Mathematizing a Shell" (Janet G. Walter and Carolyn A. Maher); (10) "Developing Students' Understanding of Exponents and Logarithms" (Keith Weber); (11) "Understanding Change: Epistemologies of Three Future Teachers

of Elementary School Mathematics" (Jennifer Chauvot); (12) "A Framework for Posing Technology-Rich Mathematics Problems" (Nicholas Oppong); (13) "Theory and Practice of Mathematics Education Reform: Including the Teachers' Voice" (Azita Manouchehri); (14) "Learning Trajectories as Tools for Supporting Teacher Change: A Case from Statistical Data Analysis" (Kay McClain); (15) "The Impact of Teachers' Content Knowledge and Attitudes on Instructional Beliefs and Practices" (Jesse L.M. Wilkins); (16) "A Length Model of Fractions Puts Multiplication of Fractions in the Learning Zone of Fifth Graders" (Karen C. Fuson and Mindy Kalchman); (17) "Listening as a Vital Characteristic of Synergistic Argumentation for Enhanced Mathematical Learning in a Problem-Centered Environment" (Darlinda Cassell and Anne Reynolds); (18) "Teacher Identity and Knowledge in Elementary Mathematics" (Susan B. Empson, Corey Drake, and Debra L. Junk); and (19) "Viewing a Reform-Based Mathematics Curriculum through the Eyes of Two Veteran Teachers" (Ann Wallace and Miriam Gamoran Sherin). (NB)

## **History and Aims of the PME Group**

PME came into existence at the Third International Congress on Mathematical Education (ICME 3) held in Karlsruhe, Germany in 1976. It is affiliated with the International Commission for Mathematical Instruction.

The major goals of the International Group and the North American Chapter are:

1. To promote international contacts and the exchange of scientific information in the psychology of mathematics education.
2. To promote and stimulate interdisciplinary research in the aforesaid area with the cooperation of psychologists, mathematicians and mathematics educators.
3. To further a deeper and better understanding of the psychological aspects of teaching and learning mathematics and the implementation thereof.

## Preface

It is with great pleasure that we at the University of Georgia host the 24<sup>th</sup> annual meeting of PME-NA as we also hosted the 4<sup>th</sup> annual PME-NA meeting exactly 20 years ago in 1982. A quick glance at the differences between then and now shows how the field has grown and changed: The proceedings that year were about 250 pages long, and there were 34 papers presented in 7 topic areas. This year the proceedings will be nearly 2000 pages long with over 200 presentations in 15 topic areas. Despite the growth of the field and the organization, the hallmarks of collegiality and open intellectual exchange remain.

The theme of this year's conference is *Linking Research and Practice*. The theme is intended to highlight the interplay between the ways that research is used in practice and the ways that research grows out of practice. The invited plenary speakers were asked to address the theme in their areas of expertise by challenging the audience to think critically about the research we do—the questions we ask, the methods we use, the contexts in which we do research, the people with whom we do research, how we communicate the results of our research, etc. We hope that those in attendance as well as those who will read these papers in years to come will be stimulated to think deeply about our roles as researchers and consumers of research.

We received over 250 proposals for sessions at PME-NA and are grateful for the work of the many reviewers who helped shape the program. We undertook only structural editing (format and references) on the final papers so as to leave intact the integrity of the authors' work.

We wish to express our appreciation to the many people at the University of Georgia who have made these volumes and this conference a possibility, including, but not limited to, Patricia S. Wilson, Margaret Caufield, Elizabeth Platt, Salli Park, Bernice Peters, Teresa Banker, Nancy Williams, Joseph Allen, Brian Wynne, and all of the faculty and graduate students in the Department of Mathematics Education.

*The Editors*

## WHAT DO WE BELIEVE ABOUT TEACHER LEARNING AND HOW CAN WE LEARN WITH AND FROM OUR BELIEFS?

Deborah Loewenberg Ball  
University of Michigan  
dball@umich.edu

Everyone seems to have strong convictions about teacher education—about what teachers need to learn, about how they can be helped to learn those things, about the factors that affect professional growth and the improvement of teaching and learning. There is widespread consensus about some claims, but significant dissent about others. Reasonable as they may seem, do we really *know* these things? In many cases, the evidence on which particular claims rely is inadequate. The claims may be true. But they may also require qualification. Some are probably dead wrong. Some compete with others, equally popular. In this session, we will consider a set of claims about teacher learning and what it would take to deploy them as resources for developing a stronger knowledge base about professional education for teaching. This paper is not intended as a review of the literature, and is also not meant to suggest that we know nothing about teacher learning. Instead, it is meant to provoke a collective discussion of how inquiry and practice in teacher education might support its development and improvement.

### **The Value of Skepticism to the Development of Knowledge**

One hot summer Sunday morning, my attention was captured by a provocative headline in the *New York Times*: “Science needs a healthy negative outlook” (Kolata, 2002). When scientific experiments are successful, noted the writer Gina Kolata, they are published, and that this is how we think knowledge grows. “But the sad truth about science is that most experiments fail and the hypotheses that seduced researchers turn out not to be true, or at least, the studies provide no evidence that they are true.” Are such studies any less important than those that we call “successful?” asks Kolata. Isn’t it success to show that something we thought was true may not be, or that what we believed may need some revision?

I often make myself unpopular among my colleagues by asking, “Do we really know that?” about some popular idea or another. My intention is neither to suggest that we know nothing, nor to be unproductively cynical. But I am as prone as anyone to accord unwarranted weight to my assumptions and preferred ideas. The *New York Times* headline gives me courage to remind myself that being wrong is useful to learning. I know this already from my experience as a teacher. Children’s errors can be exploited to make productive mathematical progress. Indeed, in mathematics, the failed proof may yield as much insight as the successful one (see, for example, Lakatos, 1976). Why should the progress of knowledge in teacher education be any different?

Perhaps it is the pressure—from funders, from the public, from our administrators and colleagues—to show that what we do works, or perhaps it is the natural internal need of teachers everywhere to believe that we are making a difference, and to think we are “right.” We take firsthand, memorable experiences and generalize them; we develop beliefs and see them at play around us; we use our operating assumptions to explain events and outcomes. It is no easy task to push oneself to consider alternative explanations, to question the reliability or validity of evidence, to see the shadows as well as the foreground, to wonder and question. Yet the capacity for surprise is at the heart of learning, the possibility of refuting hypotheses the core of good science. Scheffler (1977/1991) captures this when he writes, “Receptive to surprise, we are capable of learning from experience—capable, that is, of acknowledging the inadequacies of our prior beliefs and recognizing the need for their improvement (p. 12). And much contemporary philosophy of science reveals the importance of the deliberate effort to refute operating assumptions, of the careful pursuit of counterexample and counterevidence (Kuhn, 1962; Popper, 1963).

Disciplined inquiry depends fundamentally on both faith—the formation of strong convictions and initiatives that seek to build on those—and doubt—the deliberate effort to be skeptical about those convictions. If hypotheses are not falsifiable, for example, then learning is hampered, because experience can do no more than confirm the premises. If the data gathered cannot offer evidence that calls those premises into question, then it does not support learning. If ideas are held as principles, and never unpacked and developed, their use for practice is likely to be negligible.

### **The Challenge of Combining Action and Inquiry**

We find ourselves in a period where developments in professional education have perhaps never been more important. New professional standards, increased pressure for testing and results, new curriculum materials, and an ever-diversifying student population all imply the need for high levels of professional skill. But ours is not a highly selective profession like law or medicine. On a massive scale, we must prepare elementary and secondary teachers to begin teaching mathematics with reasonable proficiency. And, equally daunting, we need to build a culture, including structures and resources, for the ongoing professional learning that developing the complex practice of teaching mathematics requires. Rarely has the demand for teacher education and learning been as widely articulated, and rarely have as many opportunities and as much funding existed. It sometimes seems a bit frightening, for with all humility, we know that we do not know all that we need to know. Yet we must act. As teacher educators, leaders, and professional developers, we must design courses, programs, materials, and workshops. As teachers, we must choose opportunities for our own learning. This must all build on the best current knowledge, the best wisdom of practice, and on experience.

These conditions also present the field with unprecedented opportunities to develop knowledge about teacher learning and teacher education. Making clear our assumptions, beliefs, and current ideas to frame strategic working hypotheses can enable us to use practice itself as a medium for the development of such knowledge. Doing this means identifying the best of what we currently know, considering the basis for that knowledge, and actively cultivating skepticism. It means seeking disconfirming evidence, valuing negative results, and questioning the basis for our claims. Without this stance, teacher education runs the risk of being based on ideology more than wisdom. And without evidence for what we know, and the willingness to leave open that which we do not know, we have no better claim to what it would mean to create good professional development than anyone else. Our beliefs will compete, often ineffectively, with others'. And the quality of teachers' opportunities to learn will be based on caprice and personal bias rather than evidence.

### **Commonly Held—and Sometimes Competing—Beliefs About Mathematics Teacher Learning**

I turn now to a small set of ideas that are often heard as claims about teacher learning. My purpose is to consider what does—or would—make these “knowledge,” and what it would take to use these ideas as levers for developing reliable, valid, and useful knowledge about teacher education, and to avoid reinforcing ideology that limits the development of such knowledge. Grouped into a few important categories—what mathematics teachers need to know, for example, or the structure of effective professional development—some common beliefs compete with other, also commonly espoused, beliefs. The empirical bases for any of these claims vary widely. Some have been produced from studies of teacher learning and teacher education while some are part of a contemporary ideology in this country. Worth considering is how our ideas are both helpfully shaped and also limited by culture and experience. These ideas, then, have different origins, and possess uneven warrants. But, ubiquitous, they are widely held. And each makes sense, and is in some important ways, likely valid. But each also deserves to be questioned, for its basis, and likely validity. Put too simply: Where did each of these ideas come from? What about them do we know to be true? What is likely right about them? What are you suspicious about with each one? What would it take to unpack each one, to sort out its constituent ideas and assumptions, and use the results of this analysis deliberately to make progress in what we know about teacher learning?

1. The pedagogy and curriculum of mathematics courses for teachers  
Mathematics courses for teachers should be designed to model the ways that teachers should teach their own students.
2. The structure of professional learning opportunities for teachers
  - (a) One-shot workshops are not effective.

- (b) Teachers learn when they can work closely with colleagues.
  - (c) Lesson study is an effective form of professional development.
  - (d) Lesson study can work in a country like Japan, but would not work here.
3. The nature and scope of the mathematics that teachers need to know
- (a) Teachers need to know mathematics of the school curriculum in depth; courses that treat advanced mathematics are useless to teaching.

Alternatively:

- (b) Teachers need to know more than they are responsible for teaching—advanced mathematics study is important to being able to have perspective and make good judgments.
4. The role of curriculum materials in mathematics teachers' practice
- (a) Highly detailed teachers' guides and curriculum materials limit teachers' professional autonomy. Teacher education should prepare teachers to work as professionals, using curriculum materials as a resource as needed.

Alternatively:

- (b) Highly detailed teachers' guides and curriculum materials can make up for lacks in teacher knowledge and experience. Teacher education should help teachers learn to interpret, adapt, and use curriculum materials.

Before reading further, it might be useful to consider your own appraisal of each of these commonly heard beliefs about the professional education and learning of teachers. For which do you think there is substantial evidence? For which do you think the evidence is sparse? Which are you inclined to agree with, and why? And with which do you take issue? On what basis?

### **The Pedagogy and Curriculum of Mathematics Courses for Teachers**

Frequently it is claimed that teachers need to learn mathematics in the same ways that their students should experience that mathematics. An alternative formulation of this idea is that mathematics courses for teachers should “model” the pedagogy and curriculum that teachers would learn to enact with students. An under-elaborated idea, it is not clear what is included in the notion of “modeling.” Somehow, however, it is thought that instructors or professional developers would work with teachers as they learn mathematics in ways similar to what those teachers should do with their own students.

The idea of “modeling” good practice is intuitively appealing. In fact, it would seem difficult to argue that the teaching should not exemplify good practice. It seems obvious that the better the teaching, the more effective the course or workshop will be. And, most important, this “good teaching” can not only help teachers learn mathematics, but it will also help them learn about teaching mathematics. However, what would

it mean for this to be something we could say we *know*, as opposed to an idea to which we are attracted?

First, it would help to unpack the idea of “modeling,” and decide what the elements are that might be modeled. A second question would be what it means for an approach to be “similar.” Without this sort of clarity in the core ideas of the claim, it is difficult to investigate it.

Second, it would be useful to consider what might make this a valid claim, and what might militate against it. On the face of it, we suspect that how ideas are taught and experienced shapes what is learned. If the point is for teachers to develop the sort of knowledge they will need when they work with students, then they may need to encounter it in similar ways. Moreover, teachers may learn about teaching from the ways in which they are taught mathematics, and so “modeling” teaching may deliberately take advantage of this to make it possible for teachers to learn about teaching mathematics even while they are learning the mathematics itself.

This leads to a sub-claim about what is learned from “models.” What do we mean when we speak of “modeling”? What do teachers actually learn from watching their instructors teach mathematics to them? How is their learning from modeling affected by whether or not the instructor narrates what he or she is doing? How is their learning affected by their opportunities to analyze the instruction?

Stepping back from the question about what constitutes modeling and what is learned from models, some observations suggest that, for all the intuitive appeal of the idea, it might not always make sense to teach mathematics to teachers as one might teach mathematics to students. After all, teachers are not eight-year-olds, and they have already been taught the mathematics that comprises much of what they encounter in teacher education. They have been taught to divide fractions, multiply decimals, to identify polygons and quadrilaterals. They have solved countless puzzles and problems. The challenge for some teachers, documented in many studies of teachers’ mathematical knowledge, is that they have learned these ideas with little meaning or connective tissue. They know the forms, but not the ideas. Sometimes they have not even really learned the forms. All of this suggests however, that as teachers approach learning mathematics, they bring different resources and foundations than do their students. So, for example, problems that are fruitful for children may not be so for their teachers. And vice versa. Take, for example, the well-known problem of constructing a story problem for  $1\frac{3}{4} \div \frac{1}{2}$  (Ball, 1988; 1990; Ma, 1999):

- (a) Calculate the answer to  $1\frac{3}{4} \div \frac{1}{2}$ . What do you get? What method did you use to get the answer?
- (b) Write a story problem, or describe a situation, for which  $1\frac{3}{4} \div \frac{1}{2}$  is the mathematical formulation. What do you get? How does it fit with the answer you got when you calculated?

While most preservice and practicing teachers remember the procedure of “invert and multiply” and can get  $3\frac{1}{2}$  for the calculated answer, most cannot produce a story problem that correctly maps to this expression. Instead, most stories involve dividing by 2 rather than  $\frac{1}{2}$ . A typical story is:

*I had two pizzas. My roommate ate  $\frac{1}{4}$  of one of them, and then I had  $1\frac{3}{4}$  pizzas left.*

*I shared the remaining pizza with one of my friends. How much pizza did we each get?*

Automatically assuming the pizzas to be divided into fourths, many imagine the following:

This representation results in each of two people getting  $3\frac{1}{2}$  pieces. What people do not often notice is that this solution changes the unit from halves to quarters. Each person in the pizza story is getting  $3\frac{1}{2}$  *quarter-pizzas*, not  $3\frac{1}{2}$  *half-pizzas*. (Worth noting is that this common “solution” to the problem of generating an appropriate story problem is produced by most adults—not just teachers—to whom the question is posed.) What is important for the present discussion is that this problem, posed to a group of teacher education students or practicing teachers, can be fruitfully used to develop a number of significant mathematical ideas, including interpretations of division, the importance of the unit, and what is involved in building a mathematical correspondence between a model and a mathematical expression. That this is a fruitful workspace seems related to the fact that the arithmetic territory is not new to them, that the work is engaging them in a disequilibrating encounter with something they already know. This would *not* make a good problem for sixth graders first learning to divide fractions. They would not be able to calculate with such ease, nor use the algorithm of “invert and multiply” to produce the initial answer. The discrepancy between the calculated answer and the story problem would not emerge, and there would not arise the surprise factor that animates adults’ learning in this problem.

Developing the concept of division and extending it to fractions, as one would do with sixth graders is a different pedagogical undertaking than challenging complacent procedural knowledge of adults. That teachers already know a great deal of mathematics, albeit often without deep knowledge of the fundamental ideas, makes productive mathematics learning experiences often different for the two groups. Hence, the simple adage that teachers should be taught as they would teach students, is likely *too*

simple. The mathematics *problems* that afford appropriate intellectual space for students' learning are often different from those that afford learning spaces for teachers. Teachers would not necessarily profit from problems designed for student learning. And problems that are designed to be fruitful for teachers may not set up students' learning as well.

Treating as a working hypothesis this reasonable idea that professional development should "model" the mathematics teaching that teachers should use with students would involve examining the sorts of mathematical tasks that seem to afford productive learning for teachers, and for students. It might also involve close analyses of the interactive dynamics of mathematics discussions among teachers, compared with those of children. Just as there may be some distinctive features of problems that are fruitful for teachers' learning, there may also be particular possibilities or challenges in helping teachers work—independently and with others—on mathematics. Their histories, identities, and understanding are all likely different in some important ways from those of students, and good pedagogy is about building bridges between learners and the mathematics to be learned. Engaging this principle as a hypothesis rather than mandate would likely uncover interesting areas of overlap between the teaching and learning of children and the teaching and learning of teachers. Doing so would require careful unpacking of the constituent elements of the claim, and scrutiny of their validity in a variety of contexts and under different conditions. Are the issues different for beginning versus experienced teachers? For elementary versus middle or high school teachers? Does it matter what the mathematical content is? For example, does it make a difference if the mathematics to be learned is *new* to teachers—that is, not content that they are revisiting, but content they have never explored before? Does it matter if the purpose of their work is to prepare them to work on it with students versus to develop some broader sense of the territory, some sensibilities or peripheral vision? And throughout, what we need is a thoughtful development of what "modeling" might involve, and what it would take for it to be educative.

There are also important teacher learning questions involved in this set of ideas. What might it mean to approach an opportunity to learn mathematics as a teacher rather than as a student? And are there versions of such a stance that would make more mathematics courses and workshops into useful sites for developing mathematical knowledge, with less reliance on the instructor's ability to model a particular pedagogy? For example, a limiting version of such a stance might mean that a teacher would see as irrelevant forays into mathematical ideas and issues not directly related to the curriculum. But generative versions of such a stance might mean that a teacher would actively take note of others' mathematical ideas in the session as a window into how others might solve a particular problem or understand a specific idea. Or, a teacher, aware of the sort of depth and flexibility of understanding needed in teaching, might not settle for getting right answers, and be more demanding of himself or her-

self, and of the instructor to reach for a stronger sense of the ideas. While the notion of “modeling” may include some important claims worth unpacking about what instructors can do, there may be some parallel ideas about what it means to learn mathematics as a teacher that may be worth uncovering and exploring as well.

### **The Structure of Professional Learning Opportunities for Teachers**

Many hold strong beliefs about what constitute productive structures for teachers’ learning. Widely believed is that “one-shot workshops”—that is, single session professional learning opportunities, without follow-up—are not useful. And many believe that when teachers work with colleagues, the time spent is worthwhile. Reactions to the newer phenomenon that is referred to as “lesson study” are similarly impassioned, often also related to structure of the work, and the professional and social features of the learning opportunities. Although likely important in combination with other more “curricular” aspects of professional development, *what* teachers work on—the curriculum of the professional learning—seems likely to be as big a factor as the *structure* of the opportunity. Notably relevant is that organizational features of students’ learning of mathematics have not been shown to have effects on their learning of mathematics on their own. This should give pause to strong claims about the effects of structure on teachers’ learning.

Why might we believe such claims? Let’s take the “one-shot workshop” first. One reason to disparage such formats is that most of us, whether teachers or teacher educators, have seen or participated in shoddy one-shot teacher “inservice” sessions. We have had strong reactions to the waste of time, to the lack of engagement or useful knowledge, to the often-poor pedagogy or dramatic style of such sessions. Yet many school districts continue to provide such opportunities, and many of us have ourselves offered such sessions. We may even think that some of what we do in such sessions has value, and may also hear from participants that they found them useful. Reflecting further, many of us may have also had important insights in the context of a single session—a lecture, a workshop, a meeting—that turned out to be significantly generative for our learning. Taken together, there may be more to ponder than at first meets the critical eye. If in fact, districts are likely to continue sponsoring such sessions, there are good reasons to investigate the sorts of experiences, content, and ways of working that *can* be productively packaged into single sessions.

Moreover, and equally important are the teacher learning questions involved. Teachers, like most professionals, have many opportunities to learn and to develop their knowledge, skill, and practice. What does it take to be a good user of professional learning opportunities—to combine different kinds of learning, to use sessions and people as resources in an ongoing learning program of one’s own? In other words, what would it mean to be a discriminating and constructive user of multiple forms of professional development, across sessions, workshops, courses, meetings—with one’s own needs for learning and one’s own practice as the drivers? Viewed from the

perspective of the teacher as a learner, a series of one-shot workshops that the teacher coordinates in his or her own learning may have more coherence and value than can be seen by the outside observer.

The current enthusiasm for and concomitant skepticism about “lesson study” is no more than a specific case of the claims often made about forms of teacher education. Made visible through the popular book, *The Teaching Gap* (Stigler & Hiebert, 1999), and actively developed in research and development programs such as those led by Catherine Lewis (Lewis, 2000) and Clea Fernandez (Fernandez, Chokshi, Cannon, & Yoshida, in press) and their colleagues, “lesson study” is a term given to describe a kind of professional work in which Japanese teachers engage to develop their teaching. Probing the surfaces of the practices involved in lesson study suggests that there are important aspects of this work that offer promise for teachers to learn in and from practice, in the company of other professionals. Teachers work closely on a particular mathematical idea, examining its elements and connections, probing ways it might be represented to students, and investigating difficulties children might have in learning it. They collaborate to design and teach the topic to students, testing their design ideas in practice, analyzing how they work, and revising and reteaching the lesson.

This cycle of study and development in practice offers some important opportunities for teachers’ learning. It also shares family resemblances with other forms of professional learning being explored in the United States and in other countries—the use of cases, for example, or the study of videotapes or other records of practice. Learning from experience is difficult. It is also both essential and inescapable. What these different forms of professional development share is the attempt to “harness” practice to make it a productive site for professional learning. Closer analysis of the underlying ideas and the ways in which they are enacted would afford important possibilities to gain knowledge about how teachers can learn in, from, and for practice (Ball & Cohen, 1999).

Yet some of the current attention to lesson study does not yet probe its fundamental conceptual structure as an opportunity for teacher learning. Ironically, both its proponents and its skeptics can at times remain focused on its external structure and form. People ask questions such as: How much time do teachers spend? How often do they meet? How many lessons do they work on in a year? While its forms matter, what is significant about lesson study is probably not merely those forms. Most likely what is significant is not mainly that teachers work with one another. It is more likely that what matters is the unusual ways in which it engages teachers in learning mathematics in ways connected to practice. Also important may be the work on lesson design that organically connects attention to student thinking and to the integrity of the mathematical ideas. If the structures used in Japan do not fit the common organization of teachers’ work in the U.S., this provides fodder for discussion. But if these structures are taken as the dominant feature, then the possibilities of learning about the interplay of structure and what teachers work on, and in what ways, are limited.

Lesson study is no more than an instance of a larger challenge we face in developing knowledge about teacher learning and teacher education. Surely the structures of teachers' opportunities to learn do matter. But to develop what we know beyond claims about surface features of professional education, we will need to unpack the dynamics of form and content—of what teachers do, in what forms, and what sorts of professional learning by teachers occur across different permutations of these.

### **The Nature and Scope of the Mathematics that Teachers Need to Know**

Many strong views exist about what teachers need to know. Few, however, are based on more than anecdotal or small-scale evidence about how teachers' knowledge of mathematics affects their effectiveness with students. Yet because mathematical knowledge for teaching is a domain that also lends itself to logical analysis, countervailing claims permeate the discussion, each with reasonable bases. Professional opinion provides the foundation for many claims in this arena. However, few disciplined means exist for sorting out these competing claims. It makes sense to claim, for example, that what teachers most need is to understand the mathematics for which they are responsible. In order to teach multiplication of decimals well, for instance, there is much to understand about number and operations, about models for each, and about algorithms and place value, about the distributive and commutative properties. Yet closer scrutiny may also reveal that mathematical issues can arise as teachers work with their students, issues for which more advanced mathematical knowledge might be useful (see, for example, Lampert, 2001, for an up-close view of the mathematical complexity of elementary teachers' daily work). When students propose alternative approaches, teachers need ways to size up their mathematical validity and value in order to make sound decisions about what to take up and what to deal with individually (Ball & Bass, 2000). Seeing connections between these elementary arithmetic procedures, such as multi-digit multiplication, and ideas and work with polynomials can also offer teachers a sense of the mathematical horizons, of the trajectories along which their students are traveling. Ma's (1999) notion of "knowledge packages" offers one way to conceptualize the structure of usable mathematical knowledge, emphasizing the importance of core ideas and their connections and development over time. A close focus on the curriculum, narrowly interpreted as what teachers teach, can limit teachers' peripheral vision and lead to a kind of myopia in teaching decisions. However, it is also easy to overlook the complexity and richness important to unpack and learn right in the immediate mathematical territory. A commitment to extending teachers' mathematical reach can inadvertently shortchange what there is to learn about the ideas within the student curriculum.

So far, we see that competing claims about the extent of teachers' knowledge are viable, based on reasoned argument. However, significant problems exist that limit our progress on this important set of issues. First, we lack specificity about what it might mean to learn "the mathematics of the curriculum" or to engage with "advanced

ideas.” We need ways to make these notions more concrete and be able to develop indicators or measures of each, and of other conceptions of teacher knowledge. And we need to be able to track and analyze how different kinds of mathematical knowledge bear on practice. How, for example, do teachers with different kinds of mathematical understanding appraise and use curriculum materials? How do they size up the mathematical quality of alternative materials, perceive and compensate for distortions, transform weak presentations, learn from unfamiliar but promising representations or approaches? Evidence on these and other such questions about practice would help to mediate these different claims. It is even possible that the more closely tied to practice the discussion becomes, the closer, too, will grow the different claims. And remaining to study, most important, is how teachers’ mathematical knowledge affects what their students learn. Progress on this question depends on developing the sort of more nuanced conceptions of what might be meant by “knowing mathematics for teaching,” for the past efforts to use proxies for teachers’ mathematical knowledge (e.g., courses taken, degrees held) have generally been too imprecise to detect effects.

It may also be too imprecise to view all mathematical knowledge similarly. Perhaps the nature of knowledge for teaching depends on the ideas themselves. For example, maybe knowing geometry for teaching is qualitatively different from the knowledge needed to teach number and operations. What about elements of mathematical knowledge that are less topical—knowledge about the nature and role of mathematical definitions, for instance, or mathematical reasoning? It may also be that some mathematical ideas and skills have high leverage for teachers’ mathematical proficiency in teaching. Possibly certain elements of mathematics not easily considered “knowledge” have significant power in teaching. Examples might include sensibilities about what makes a mathematical solution elegant, fascination with symmetries and correspondences, appreciation of particular representations, sense of a good problem. Might it be that these mathematical qualities and orientations bear in important ways on teachers’ decisions and capacities? Investigating these and other questions about the mathematical resources that matter for teaching requires moving beyond the sort of blunt (e.g., numbers of courses) or vague (e.g., descriptors such as “deep” or “flexible”) claims about what teachers need to know. It requires a closer probing of mathematics itself and what there is to know and appreciate about the domain. It requires also an equally closer probing of the mathematical demands of teaching, and improving our working hypotheses in ways that will allow us to test and develop our claims.

### **The Role of Curriculum Materials in Mathematics Teachers’ Practice**

Do curriculum materials hamper or enable teachers? Strong views run in different directions on these questions, complicated by equally strong views about the quality of any particular textbook. Some are sure that textbooks determine the curriculum; others are convinced that teachers are a bigger determinant than the materials they use. Perhaps it is because teaching is a mass profession, or perhaps because of the impor-

tance of design and development in learning, curriculum materials do play a visible and important role in instruction. Much evidence suggests that despite an ideology that suggests that teachers who “make” their own curriculum are more “professional,” commercially published curriculum materials dominate teaching practice in the U.S. (Goodlad, 1984). This role may be greater in mathematics teaching even than in other subjects. Textbooks provide a structure and organization for the ideas and skills, and order the development of content over time. With both assignments for students and guidance for teachers, curriculum materials are a relatively elaborated resource for teaching. Unlike frameworks, objectives, assessments and other mechanisms that seek to guide curriculum, instructional materials are concrete and daily. They are the stuff of lessons and units, of what teachers and students do. That centrality affords curricular materials a uniquely intimate connection to teaching. An important question, then, is how teachers use them, and how much and what aspects of curriculum developers’ visions are enacted in classroom lessons.

Because of this close connection to the daily work of teachers, the design and spread of curriculum material is one of the oldest strategies for attempting to influence classroom instruction. Reformers have often used instructional materials as a means to shape what students learn (Bruner, 1960; Dow, 1991) and some developers have operated as though curriculum materials could operate nearly independently on students (Dow, 1991). Recent strong efforts in states such as California and Texas reflect policymakers’ assumption that controlling textbook adoption will determine the curriculum. Critics argue that this strategy “de-skills” the professional work of teaching and severely limits local discretion over curriculum (Apple, 1990). Many of the recent debates in mathematics education have centered on this set of issues: on arguments about curriculum materials, their endorsement and adoption, their evaluation and effects.

However, too little is known about how teachers use textbooks, or more, what they learn from them. Long-term research on teachers’ content decisions by Porter and his colleagues (e.g., Schulle, Porter, et al., 1983) suggest that teachers’ mediate curriculum developers’ designs and intentions. And many researchers claim that teachers include and omit lessons, follow and modify teachers’ guides, as a function of their own knowledge and beliefs about mathematics, learning, students, and goals (Fennema & Franke, 1992). Still, while some argue for highly elaborated materials with detailed teachers’ guides, others claim that such curriculum materials deny teachers professional discretion. Here, as in other areas, ideology and evidence co-mingle. Imagine another profession where the essential tools of the trade were as contested as textbooks are in teaching. The notion of a “professional” creating his or her own tools *de novo* is not only impractical; it is both risky and foolish. None of us would prefer surgeons who departed from detailed protocols for particular procedures or who defined professionalism as the right to be creative and find one’s own style. A recent

essay in the *New Yorker* illustrates just how complex is the learning to use and carry out such procedures effectively, and how long is the “learning curve” in doing so (Gawande, 2002). To complicate matters further, as in teaching, professional practice changes across a surgeon’s career, making it necessary to continue learning new procedures, approaches, and ideas.

Yet even to agree that curriculum materials provide important tools for instruction does not answer major questions about what makes curriculum materials usable, what makes them resources with and from which teachers can learn, and what might constitute the needed guidance for the necessarily particular nature of helping children learn mathematics. Turning our beliefs and worries about the role of curriculum materials in teachers’ learning and in their practice demands a closer examination of what might be meant by “guidance” and ways to distinguish among different kinds of detail in materials. Are some forms of detail prescriptive and inflexible, while others provide specifics that are usable and adaptable? How do teachers read and use different kinds of material, and what factors seem to influence differences in teachers’ uses? Do some materials make it possible for even relatively inexperienced teachers, or teachers with weaker mathematics backgrounds, to teach well, while others are most useful to very skilled teachers?

Learning more about how curriculum materials might function in practice requires setting aside worries and ideologies, and turns assumptions about teachers and teaching into questions that can be investigated in relation to teacher education and learning over time. Although this set of ideas pertains to instruction rather than to teacher education, it is important because of the centrality of curriculum materials in mathematics teaching. A recent study (Cohen & Hill, 2001) suggests that professional development may be more effective when teachers’ opportunities to learn mathematics, and to learn about how to help students learn that mathematics, are connected with the materials they use. What we understand about the interplay of curriculum and teachers in teaching can contribute significantly to our ideas about teacher learning and teacher education. What do teachers need to learn to appraise, interpret, and use curriculum materials wisely? How might professional education and curriculum be designed to work together more effectively in improving the quality of mathematics instruction and in helping teachers develop their practice?

### **On Knowing What We Know**

The domains briefly explored above are riddled with beliefs. Firsthand experience, anecdotes, and commitments can lead to strong views about good professional development, what mathematics teachers need to know, or how textbooks shape instruction. But in each of these areas—as in any others we might explore—opposing views compete without grounding to mediate their claims. Our arguments are based as often on firsthand perspectives and personal experience or anecdote as on more rigorous evidence. Even where we do have better evidence, that evidence is often currently

limited in a variety of ways that matter for our claims to “knowledge.” Our evidence in some cases does help to support our ideas, but there is more to ask, and to investigate. For example, we have not put in the foreground the “who” of teacher learning as often as we might. We tend to know only of teachers who stay *in* professional development, or who *do* participate in programs, workshops, or who pilot materials. What might be learned by following those who leave professional development, who work more on their own, who do not work closely with university educators? What about preservice teachers who are less visible or less enthused about their education classes or their mathematics courses, who are more or less engaged? There are also important questions about generalizability. What of teachers in contexts where less research has been done on teacher learning, where fewer interventions are tried, where resource conditions and the contexts of practice are different? What about beginning teachers versus teachers with many years of experience? Or teachers with substantial depth in mathematics for teaching compared to those without? Does who the teacher is, or where he or she works, shape the usefulness of different ideas, programs, or approaches?

There are questions based on *how* we work, as well as with whom. For example, many opportunities for teachers’ learning are designed based on one view or another, without the possibility of scrutinizing the validity of any particular claim. For example, mathematics courses are offered for teachers that engage them in advanced study, while others aim to probe the intricacies of the mathematics of the school curriculum. In some cases, deliberate effort is made to model the pedagogy teachers should use with students, in others not. Some professional development is strategically tied to specific curriculum materials while other programs offer supplementary material and ideas, unconnected to any particular textbook series. In general, opportunities for teachers’ learning are designed based on the views held by those who develop and run any particular experience. Only rarely are these assumptions articulated as such, and even less often are they systematically tested. If more such deliberate articulation, design, and delivery could be designed, and then followed, we might be able to engage in various forms of comparative analysis. Doing this would engage us in a useful discussion about evidence.

Wilson and Berne (1999), surveying the practice of professional development, and our beliefs about it, note that the qualities of high-quality teacher professional development can be found in lists sprinkled through our literature. These lists are highly consistent, and, they note, perfectly reasonable. “Yet we know as little about what teachers learn in these kinds of forums (conforming to the principles which we embrace) as we do about what teachers learn in traditional staff development and inservice. Our readiness to embrace these new principles may, in fact, be rooted in a desire to escape collective bad memories of drab professional development workshops rather than sound empirical work. Replacing our old conceptions of professional development with new only makes sense if the new ideas are held up for rigorous

discussion and evaluation. New isn't always right." (Wilson & Berne, 1999, p.176) In their review of four thoughtful intensive professional development programs, each focused on subject matter instruction in a particular area, Wilson and Berne (1999) acknowledge the complexity of the work, but prod: Too often, examination of program effects was based on teachers' reflections on what was useful and helpful, comments about what they used, and reports of what they learned. While participants' reactions are obviously important in seeking to understand how teachers experience particular learning opportunities, imagine if we relied on children's reports of what was helpful for our examination of the effectiveness of particular instructional approaches. Wilson and Berne push for more developed methods of studying what teachers actually learn, and how, and for how what they learn affects their effectiveness with students. They note that the progress of the field depends on more systematic ways of studying what teachers learn and how this affects what they do, and more careful examination of how teachers learn inside of particular approaches and experiences.

Our charge, then, is to take our fond beliefs and current ideas, and turn them into explicit working hypotheses that can be tested, compared, and falsified in a variety of settings, and with different kinds of teachers. If all we do is create programs for professional learning based on what we currently believe and then generate illustrations of how these ideas play out in practice, we do not push our ideas nor test them. We do not make progress as a field, and we condemn ourselves to a morass of endless irreconcilable arguments about the quality and effects of professional development.

So, for instance, we need to articulate more clearly what it means to "model" good teaching in professional development, and what, specifically, it would mean to teach teachers as they should teach students. We need to track closely how this might be done, and examine critically what teachers attend to, how they interpret what they experience, see, and discuss, and what impact this has on what they know and believe and what they do. And we need to compare different ways of enacting the principle of "modeling" good instruction. Only if we collectively and individually develop ways to isolate our most compelling current ideas, and subject them to testing, questioning, and study, will we be able to make the sort of progress that the field needs.

Our beliefs are resources for such progress if we wield them as hypotheses rather than mantras. It is to that endeavor that this session intends to turn us. Instead of arguing about the mathematics requirements needed for certification, without grounding or evidence, ask: what difference *does* advanced mathematical study make to teachers' mathematical resources, or to any aspect of the practice of teaching, and how could we know? How *do* teachers use textbooks and what do they learn as they use them? How *does* professional development interact with the materials that teachers are using? Or take the one-shot workshop: Are there *no* things that lend themselves to this format, and how could we find out? Are there things one might try to do within such workshops that would intervene in their assumed limitations?

Converting assumptions to empirical questions, beliefs to testable hypotheses, and ideology to theory, the field of teacher learning and teacher education will begin to develop more reliable, warranted knowledge—and new and more subtle and sophisticated ideas that can, in turn, be tested. Not only do we need to deploy our ideas as questions, but we need also to think more systematically about where and with whom we investigate these questions. How can we design work such that we test ideas across settings and with teachers with different backgrounds, levels and kinds of experience, attitudes and needs? Developing a self-critical and constructive enterprise in which we seek to use our well-honed beliefs as resources for the development and improvement of our knowledge about teacher learning and teacher education is an endeavor well worth our collective commitment and engagement.

# **TOWARD EVIDENCE FOR INSTRUCTIONAL DESIGN PRINCIPLES: EXAMPLES FROM COGNITIVE TUTOR MATH 6**

Kenneth R. Koedinger  
Carnegie Mellon University  
Koedinger@cmu.edu

There is a significant gap between theories of general psychological functions on one hand (e.g., memory) and theories of mathematical content knowledge on the other (e.g., content of algebra). To better guide the design of ground breaking and demonstrably better mathematics instruction, we need instructional principles and associated design methods to fill this gap in a way that is not only consistent with psychological and content theories but prompts and guides us beyond what those theories can do. Toward this goal, I reflect on lessons from past and current Cognitive Tutor mathematics projects. From this experience, I have abstracted four instructional bridging principles, Situation-Abstraction, Action-Generalization, Visual-Verbal, and Conceptual-Procedural, and associated methods for applying them. I illustrate these in the context of the design of the successful Cognitive Tutor Algebra course (now in more than 800 schools) and the on-going research and development of a Cognitive Tutor course for 6<sup>th</sup> grade mathematics.

## **Introduction**

My first goal in this paper is to summarize a successful educational innovation grounded in psychological research on mathematical learners and learning. Cognitive Tutor Algebra is a full year course that combines a problem-based consumable textbook, used 3 days a week, and intelligent tutoring software, used 2 days a week. Cognitive Tutor Algebra has been successful commercially, sold to over 800 schools, and pedagogically, shown to yield higher student achievement than alternatives. My second goal is to summarize aspects of the psychological theory, ACT-R, that supported the design of this course and helps explain its apparent success. My third goal is to motivate the need for theory at an intermediate level between general cognitive theories, like ACT-R, and models specific to narrow content areas, like proportional reasoning. Such theory is needed to fill the gap that exists between general theory and instructional innovations, so that fewer unguided, purely intuitive decisions need to be made in instructional design. I will discuss four principles to guide such decisions and describe domain-specific methods to implement these principles. My fourth and final goal is to introduce a new Cognitive Tutor mathematics course for 6<sup>th</sup> grade and to illustrate the four principles using text and tutor lessons from the on-going course development.

## **Success of Cognitive Tutors and Humility Message**

Before discussing the Cognitive Tutor Algebra project, let me start with some background. Following an experience creating and field testing an intelligent tutoring

system for geometry proof (Koedinger & Anderson, 1993), in which I was one of four teachers involved, it became particularly clear to me how difficult and important it is to attend to the social context of an educational innovation (cf., Lehrer, Randle, & Santicillo, 1989; Schofield, Evans-Rhodes, & Huber, 1990). Two key features of the social context are integrating the innovation with other aspects of the curriculum and innovation-specific teacher professional development. When we started the algebra project in 1992, we took what we called a “client-centered approach” and sought guidance from mathematics educators toward meeting national standards (Koedinger, Anderson, Hadley, & Mark, 1997). Perhaps most importantly, we decided that to address the curriculum integration challenge, we would create a full course including both the text materials (used 3 days a week) and the technology (used 2 days a week). The mathematics curriculum supervisor for the Pittsburgh Public Schools, Diane Briars, pointed us to teacher Bill Hadley who had already been writing new algebra text particularly focused on helping students make sense of algebra. We worked together, combining classroom intuition and cognitive science, to produce a problem-based course that connects multiple representations of functions and employs advanced computational tools. Problems and projects in both the text and software connect to real-world uses of algebraic reasoning like estimating the cost of a rental car, choosing between long-distance phone services, predicting the decline of the condor population, planning profits for shoveling snow, comparing the current quantity and growth rate of old growth forest in the US to the harvest rate.

In three full-year multi-school field studies, we demonstrated that students in a Cognitive Tutor Algebra course learn more than students in comparison classes both on assessments of problem solving and representation use and on standardized assessments of basic skills (Koedinger et al., 1997; Koedinger, Corbett, Ritter, & Shapiro, 2000). As the dissemination of the algebra course was ramping up, in 1995 we obtained funding from local foundations (Heinz, Buhl, Grable, Mellon, and Pittsburgh Foundations) to create full courses for geometry (led by myself) and algebra 2 (led by Albert Corbett). With the help of Carnegie Mellon’s technology transfer office, in 1998 we created Carnegie Learning, Inc to further develop and market all three courses. The number of schools using Cognitive Tutor Algebra has roughly doubled each year and is now over 800.

Such success is encouraging, but the job is not done. Education is a very hard problem. Besides tough issues of values, culture, race, politics, respect for teachers, testing, etc., we certainly have not cracked how the mind works or how learning is best achieved. We need to *remain humble*. We need to recognize that our instructional beliefs, practices, theories may be wrong. We need to put them to the test and be proud of failure. In the context of hypotheses and principles, failure advances theory. Given the difficulty of the education problem, we also need to collaborate. No one can successfully tackle a significant educational problem alone. We need to combine expertise

from multiple domains, particularly education researchers, cognitive psychologists and learning scientists, but also anthropologists, computer scientists, measurement, policy experts, etc.

In the remainder of this paper, I reflect upon the lessons learned in our Cognitive Tutor projects particularly at the level of principles and design methods. I illustrate these primarily with examples from the on-going research and development of the Cognitive Tutor course for 6<sup>th</sup> grade mathematics. In 1999, with support from Carnegie Learning, we began a project to create full Cognitive Tutor courses for middle school mathematics with Albert Corbett leading the 7<sup>th</sup> and 8<sup>th</sup> grade course development and myself leading the 6<sup>th</sup> grade course development.

### Theory, Principles, and Methods behind the Design of Cognitive Tutors

#### ACT-R and General Principles for Instructional Design

Cognitive Tutors are based on the ACT-R theory of learning and performance (Anderson & Lebiere, 1998). The theory distinguishes between tacit performance knowledge, so-called “procedural knowledge” and static verbalizable knowledge, so-called “declarative knowledge”. According to ACT-R, performance knowledge can only be learned *by doing*, not by listening or watching. In other words, it is induced from constructive experiences—it cannot be directly placed in our heads. Such performance knowledge is represented in the notation of if-then production rules that associate internal goals and/or external perceptual cues with new internal goals and/or external actions. Three examples of English versions of production rules are shown in Table 1, which is discussed below.

Developing Cognitive Tutor software involves the use of the ACT-R theory and empirical studies of learners to create a “cognitive model”. A cognitive model uses a production system to represent the multiple strategies students might employ as well as their typical student misconceptions. The following provides a simplified example from algebra equation where these three production rules are alternative ways to respond to the same goal (a, b, c, and d are any numbers and x is any variable to be solved for):

Strategy 1: IF the goal is to solve  $a(bx+c) = d$   
THEN rewrite this as  $bx + c = d/a$

Strategy 2: IF the goal is to solve  $a(bx+c) = d$   
THEN rewrite this as  $abx + ac = d$

Misconception: IF the goal is to solve  $a(bx+c) = d$   
THEN rewrite this as  $abx + c = d$

The cognitive model is used with an algorithm called model tracing to follow students through their individual approach a problem. In so doing, the tutor is able to provide context-sensitive instruction. The cognitive model is also used by an algorithm called knowledge tracing that assesses students’ knowledge growth as they succeed or

fail on actions associated with the production rules in the cognitive model. The results of knowledge tracing are displayed with “skill bars” in the computer tutor interface (see the top right in Figure 5) and are used to select activities and adapt pacing to individual student needs. The cognitive model is not only the key workhouse within the automated Cognitive Tutors, but it is also a theoretical tool used to guide the design of other aspects of instruction including problem and interface design, text materials, and classroom activities.

In 1995, we published a report on the status of the lessons learned to date from Cognitive Tutor development (Anderson, Corbett, Koedinger, & Pelletier, 1995). We described some general Cognitive Tutor design principles consistent with ACT-R and our research and development experience to that date. A key principle recommended to “represent student competence as a production set”. In other words, to base instruction on an analysis not of mathematical content per se, but of the way in which students think about the content. The notion of “theorems in action” (Nunes, Schliemann, & Carraher, 1993; Vergnaud, 1982) is very similar to production rules.

The idea here is to characterize how students may think about mathematics differently (“informally” or “intuitively”, Resnick, 1987) than is normatively taught or present in textbooks (e.g., see production #1 in Table 1). In addition, production rules represent not just *how* students think about mathematics operations, but *when* they retrieve relevant knowledge. This feature of production rules is critical to representing the fact that the knowledge students acquire is sometimes overly specific, so it does not transfer well, and is sometimes overly general, so it leads to errors. In other words, students’ “theorems in action” are often more specific than actual theorems or rules. For instance, students can combine like terms in an equation when coefficients are present (e.g.,  $2x + 3x \Rightarrow 5x$ ) but not when a coefficient is missing (e.g.,  $x - 0.2x$ ). See production #2 in Table 1. Alternatively, students’ theorems in action are often more general than actual theorems or rules. For instance, they may learn to combine numbers by the operator between them (e.g.,  $2 * 3 + 4 = x \Rightarrow 6 + 4 = x$ ) without acquiring knowledge that prevents order of operations errors (e.g.,  $x * 3 + 4 = 10 \Rightarrow x * 7 = 10$ ). See production #3 in Table 1. It should be clear that the “rules of mathematics” and the “rules of mathematical thinking” are not the same.

A fundamental assumption of ACT-R is that people learn by doing as the brain generalizes from one’s explicit and implicit interpretations or “encodings” of one’s experiences. This assumption is, in my opinion, quite consistent with constructivism. It is not the information or even the instructional activities students are given per se that matters, but how students experience and engage in such information and activities that determines what knowledge they construct from them. Thus, another principle in Anderson et al. (1995) was “provide instruction in the problem-solving context”.

The strength of ACT-R and the principles summarized in Anderson et al. (1995) are that they are general and can apply in multiple domains. However, this strength of generality comes with a limitation. An instructional designer can easily apply the

**Table 1.** Example Production Rules

| Production Rules in English  | Example of its application  |
|--|---|
| 1. Production acquired implicitly<br>(not explicitly taught)<br>IF you want to find Unknown and the<br>inal result is Known-Result and the last<br>step was to apply Last-Operator to Last-Num,<br>THEN work backwards by inverting<br>Last-Operator and applying it to Known-Result<br>and Last-Num | Part of informal “unwind”<br>strategy that solves problems of<br>the form “ $3x + 48 = 63$ ”<br>without by working backwards:<br>$63 - 48 \rightarrow 15 / 3 = 5$ |
| 2. Overly specific production<br>IF “ $ax + bx$ ” appears in an expression<br>and $c = a + b$<br>THEN replace it with “ $cx$ ”   | Works for “ $2x + 3x$ ” but not for<br>“ $x + 3x$ ”   |
| 3. Overly general production<br>IF “ $\text{Num1} + \text{Num2}$ ” appears in an expression<br>THEN replace it with the sum  | Leads to order of operations<br>error: “ $x * 3 + 4$ ” is rewritten<br>as “ $x * 7$ ”   |

theory and principles in multiple ways, some good, some OK, and some bad. For instance, the principle “minimize working memory load” can be implemented in many ways including having the technology perform trivial operations for students. However, this approach will only be effective if the designer is right about what is trivial. Getting the application of the theory and principles right depends on getting domain-specific details right. *Thus, a general theme of this paper is that we not only need to make progress in better articulating theory and principles, but also in specifying associated methods that better ensure these principles will be appropriately applied.* This point applies as well to other proposals for instructional principles.

### **Instructional Design Principles require Empirical Methods to Successfully Implement**

The National Research Council’s volume *How People Learn* (Bransford, Brown, & Cocking, 1999) proposes three general instructional principles: 1) build on prior knowledge, 2) connect learning of facts and procedures with conceptual learning, and 3) support meta-cognition. These are common to many other approaches. To take the

first, for instance, the NCTM states: “Students must learn mathematics with understanding, actively building new knowledge from experience and prior knowledge,” (NCTM, 2000, p. 16). Romberg & de Lange (2002) describe the Realistic Mathematics Education approach as recommending “making use of students informal mathematical activity to support their development of more formal strategies”.

But, what prior, informal knowledge do students have? Sometimes theoretical analysis is used to predict prior knowledge under the assumption that smaller component tasks are more likely to tap prior knowledge than larger whole tasks (cf., Van Merriënboer, 1997). Such analysis focuses on mathematical content and its external forms. However, smaller tasks are not always simpler. It is not the surface form of tasks or external representations that determine how accessible they are to students. Instead, it is the internal mental representations that students acquire and use in task performance that determines what will be simple or not. Thus, to identify what prior knowledge students have and whether task X is going to be more likely than task Y to tap prior knowledge, it is not sufficient to analyze the content domain. Instead it is critical to study how students actually perform on tasks – to see student thinking as it really is, not as a content analysis might assume it to be.

**Results of a Difficulty Factors Assessment indicating that “smaller is not always simpler”**

Consider the three problems shown below, a story problem, word problem, and equation, all with the same underlying quantitative structure and the same solution.

*Story Problem:* As a waiter, Ted gets \$6 per hour. One night he made \$66 in tips and earned a total of \$81.90. How many hours did Ted work?

*Word Problem:* Starting with some number, if I multiply it by 6 and then add 66, I get 81.90. What number did I start with?

*Equation:*  $x * 6 + 66 = 81.90$

Which would be most difficult for high school students in a first year algebra course? Nathan & Koedinger (2000) discussed results of surveys of teachers and mathematics education researchers on a variation of this question. The survey respondents tended to predict that such story problems would be most difficult and such equations would be easiest. Typical justifications for this prediction include that the story problem requires more reading or that the way the story problem is solved is by translating to the equation.

In contrast, what we found in the two original studies (Koedinger & Nathan, in press) and in subsequent replications is that students perform best at the story and word problems (70% and 61% respectively) like these and worst at the analogous equations (42%). Clearly many students were not solving the story and word problems using equation solving. Instead they used alternative informal strategies like guess-

and-test and “unwinding”, working backwards from the result, inverting operations to find the unknown starting quantity (cf., Bednarz, Kieran, & Lee, 1996). Students had difficulty in comprehending equations and, when they did succeed in comprehending, they often had difficulty in reliably executing the equation solving strategy.

This result is important within the algebra domain. It indicates that if we want to create instruction that builds on prior knowledge, we should make use of the fact that beginning algebra students have quantitative reasoning skills that can be tapped through verbal or situational contexts. Unlike many textbooks that teach equation solving prior to story problem solving, it may be better to use story problem situations and verbal descriptions first to help students understand quantitative relationships with them before moving to more abstract processing.

However, there is also a more general message. In order to apply principles like “build on prior knowledge” we cannot assume that it is obvious what prior knowledge students’ possess. Instead, we need to do empirical studies to assess what prior knowledge students have and what forms of presentation best elicit this knowledge. To remind us of this message, we need to repeat the mantra: “The student is not like me”.

### **Cognitive Tutors are Developed Using the Design Experiment Methodology**

Assessment experiments, like the one above, that compare the effect of various difficulty factors on student performance are a common component in my instructional design approach. Such “Difficulty Factors Assessments” are one part of my version of the “design experiment” (Brown, 1992) approach. Design experiments involve theoretically motivated cycles of design, feedback, and redesign. While use of theory is critical to the approach, design experiments do not involve a linear process of applying theory to create innovations that are then tested. The approach is neither purely basic nor purely applied, but combines the goals of both. It is between “the hare of intuitive design and the tortoise of cumulative science”. In addition to theory, we rely on intuitions of multiple team members, particularly practicing teachers to help generate design ideas. We test and prune ideas in embedded cycles at different time scales (see Table 2). Some cycles are short, like a 5-minute assessment to test a prior knowledge hypothesis or feedback from a project teacher on how a lesson went today and how might it be improved for tomorrow. Some cycles are at the curriculum unit (or chapter) level, like investigating how much a unit improved learning from pre- to post-test relative to an alternative approach. A typical “parametric” study compares different versions of a Cognitive Tutor that vary on a key dimension of interest. The longest cycles are at the full course level, comparing student end-of-course performance with that resulting from alternative courses.

### **Instructional Bridging Principles**

I now describe four “instructional bridging” principles that are more specific, particularly to mathematics, than the more general principles from ACT-R and others

**Table 2.** Empirical Methods at Different Temporal Grain Sizes

---

1. Single point assessment of performance. Paper quiz or informal observation (minutes).
  2. Lab study or class pull-out. Pre-Post lesson length comparison (day)
  3. Replacement unit “parametric” study. Pre-Post unit length comparison (week/month)
  4. Full course field study. Pre-Post course length comparison (semester/year)
  3. Instructional Bridging Principles
- 

described above. I have abstracted these principles from our experience developing Cognitive Tutor courses, from associated observations and experiments, and from the mathematics education and cognitive and developmental psychology literatures. In this section, I introduce the four principles and the underlying motivation for them. In the next section, I use examples from the 6<sup>th</sup> grade Cognitive Tutor course my team is developing to illustrate an on-going application of these principles.

The four “instructional bridging” principles are:

1. *Situation-Abstraction*: Bridge from concrete situational to abstract symbolic representations.
2. *Action-Generalization*: Bridge from doing with instances to explaining with generalizations.
3. *Visual-Verbal*: Integrate pictorial and verbal/symbolic representations.
4. *Conceptual-Procedural*: Integrate conceptual and procedural instruction.

These are specific variations on more general principles like “build on prior knowledge” and “connect and integrate multiple representations of knowledge”.

Different kinds of evidence for these principles can be associated with the different kinds of studies in Table 2. One heuristic form of evidence (#1 in Table 2) assesses students’ performance to see whether one form of activity/representation is closer to students’ prior knowledge and thus easier. Another stronger form of evidence is instructional studies (#2 or #3) where an experimental comparison is made between instruction based on the principle and some other plausible form of instruction. A third less strong form of evidence is full course field studies (#4) where the experimental curriculum is consistent with the principle in question, but the comparison curriculum is not. The limitation of full course studies is that experimental and comparison curricula inevitably differ in many more ways than whether they are consistent or not with the principle in question.

### **Situation-Abstraction Principle: Bridge from Concrete Situational to Abstract Symbolic**

The “Situation-Abstraction” principle is consistent with one of the key features of the Cognitive Tutor Algebra course. It recommends instruction that uses more familiar concrete problem situations and descriptions as a bridge to powerful abstract symbolic forms. A key premise is that for many ideas and concepts, we can find concrete situations or verbal descriptions that use or communicate these ideas in ways that are more comprehensible and accessible to students than more abstract symbolic and conventionalized forms of mathematical expression. Of course, these conventional symbolic forms are crucial to powerful thinking and communication, particularly in math and science and so are critical goals of instruction. The key hypothesis is that robust competence with abstract symbols can be reached more effectively and efficiently by employing this Situation-Abstraction principle.

This principle is similar or even identical to recommendations of other approaches (e.g., Nunes, Schliemann, & Carraher, 1993; Collins, Brown, & Newman, 1989; Cognition and Technology Group (CTG), 1997). For instance, the Realistic Mathematics Education approach recommends “developing instruction based in experientially real contexts” (Romberg & de Lange, 2002, p. 9). This approach has been nicely implemented in the Math in Context curriculum (National Center for Research in Mathematical Sciences Education & Freudenthal Institute, 1997–1998).

Evidence for this principle includes a number of full-year field studies (CTG, 1997; Koedinger et al, 1997) and some unit-level studies (Brenner, Mayer, Moseley, Brar, Duran, Reed, & Webb, 1997; Nathan, Stephens, Masarik, Alibali, & Koedinger 2002). However, all these studies involve substantial curricula that vary in other ways from the comparison curricula (e.g., use of multiple representations). The theoretical rationales for the benefits of early use of concrete or authentic situations include better connection with student prior knowledge, facilitating student motivation, facilitating memory, and facilitating transfer to authentic real world goals. We need more studies to test these different underlying rationales. My colleagues and I have emphasized using situations to connect with prior knowledge and demonstrated, as described above, that certain problem situations are easier for students to understand than corresponding symbolic problems. However, we have not “closed the loop” in a scientifically rigorous way, for instance, by showing that instruction that introduces situations before abstractions leads to better learning than instruction that introduces abstractions before situations but is otherwise the same.

While this principle is well known, it is not necessarily easy to implement effectively in the classroom as Deborah Ball (1993) noted:

How do I (as a mathematics teacher) create experiences for my students that connect with what they now know and care about but that also transcend the present? How do I value their interests and also connect them to ideas

and traditions growing out of centuries of mathematical exploration and invention? (p. 375)

We should not expect that all kinds of situational support are valuable in all domains. Whether and what kinds of situational supports make sense or are interesting to students depends on the domain – a point I will illustrate below with data from the 6<sup>th</sup> grade Cognitive Tutor project.

**Action-Generalization Principle: Bridge from Doing with Instances to Explaining with Generalizations**

The “Action-Generalization” principle is also consistent with the Cognitive Tutor Algebra course. It recommends instruction that has students engaging in problem solving (doing) with specific instances of a mathematical relationship as a bridge to explaining that relationship in general terms. For instance, we might have students solve a problem for specific numerical instances (e.g.,  $2 * 4 = 8$  and  $3 * 4 = 12$ ) before having them explain what they are doing in a general form (e.g.,  $x * 4$ ; cf., Bednarz, Kieran, & Lee, 1996). Or, we might have students measure and add the angles in specific triangles before discovering the generalization and explaining it in their own words.

In the process of designing the Algebra Cognitive Tutor, we performed a parametric study in which we compared tutor versions with different orderings of questions about the problem situation (Koedinger & Anderson, 1998). One tutor version was modeled after a popular algebra textbook (Forester, 1984). Here students were asked first to define an independent variable and write an expression for the dependent quantity then asked to solve for multiple instances of the variable. Another tutor version was consistent with the Action-Generalization principle. In this version, students were first asked to solve the problem situation for a couple specific instances and then asked to write an expression for the dependent quantity. Students showed significantly greater pre-to-post learning gain in the version in which instances preceded the general expression, consistent with the Action-Generalization principle.

The Action-Generalization principle is a variation on the Realistic Mathematics Education notion of progressive formalization. Hans Freudenthal (1983) believed that “students are entitled to recapitulate in a fashion the learning process of mankind” (p. ix). This principle is also related to other recommendations for promoting student meta-cognition (e.g., Bransford et al., 1999), self-reflection, and particularly self-explanation (e.g., Chi, de Leeuw, Chiu, & Lavancher, 1994). We performed a series of parametric studies with the Geometry Cognitive Tutor (Alevan & Koedinger, 2002) comparing a textbook-like version in which students solved for measures in given figures with a self-explanation version in which students explained their problem-solving steps by indicating the relevant geometry rule. These experiments demonstrated a “less-is-more” benefit for self-explanation whereby students learn deeper,

more transferable knowledge from self-explaining even though the extra time needed for explanation means they solve fewer problems in the same instructional period. These experiments also demonstrated that such benefits can be achieved with a simple approach to explanation (referencing rules in a glossary) that is easily implemented in computer software. We are currently making progress on the more difficult task of having the software give feedback on student explanation written in their own words (Aleven, Popescu, Koedinger, 2002).

Both the algebra and geometry studies were motivated, at least in part, by results of Difficulty Factors Assessments. We had found that students were more successful at problem solving with specific instances than at explaining in general terms both in algebra (Heffernan & Koedinger, 1998) and geometry (Aleven & Koedinger, 2002). Unlike the evidence for the Situation-Abstraction principle, the evidence for the Action-Generalization principle fairly nicely “closes the loop” in the following sense. First, the two parametric studies show how a result from a single point assessment can be used to guide the application of an instructional principle to create a novel instructional design. Second, they show that the students learn more from an instructional design consistent with the Action-Generalization principle than from one that is otherwise the same, but is not consistent with the principle.

### **Visual-Verbal Principle: Integrate Pictorial and Verbal Representations**

The Visual-Verbal principle recommends instruction that helps students integrate visual, spatial, or analog representations of an idea with verbal, sequential, or digital representations of that idea. In Cognitive Tutor Algebra, the use of multiple representations of functions, the more visual graph and table representations and the verbal-symbolic situation and equation representations, is consistent with this principle. However, it was not generally or explicitly applied. This principle is an expression of a major theme of the work of Robbie Case and colleagues (Griffin, Case, & Siegler, 1994; Kalchman, Moss, & Case, 2001). Case observed that students typically come to a new idea both with relevant visual intuitions (e.g., sense of size of quantities) and relevant verbal knowledge (e.g., knowing the counting sequence: one, two, three...). He suggested that deeper understanding and competence comes from a careful integration of this visual and verbal knowledge into a “central conceptual structure”. Case and colleagues have successfully employed this principle in at least three areas, early number, rational number, and functions (Kalchman, Moss, & Case, 2001). Typical results show students in experimental conditions with poorer backgrounds (e.g., low SES 4 year olds) learning more than students in control conditions with similar backgrounds and catching up or exceeding students in control conditions with better backgrounds (e.g., high SES 4 year olds).

Another influence on this principle is the Singapore Primary Mathematics textbook series (Singapore Ministry of Education, 1999), the preface of which states:

The main feature of the package is the use Concrete => Pictorial => Abstract approach. The pupils are provided with the necessary learning experiences beginning with the concrete and pictorial stages, followed by the abstract stage to enable them to learn mathematics meaningfully. (p. 3)

This statement and the associated materials combine (and confound) aspects of the Situation-Abstraction, Action-Explanation, and Visual-Verbal principles. However, visual “pictorial” representations are clearly emphasized.

### **Conceptual-Procedural Principle: Integrate Conceptual and Procedural Instruction**

The Conceptual-Procedural principle recommends instruction that supports learning of both conceptual and procedural knowledge and facilitates students in integrating the two. Rittle-Johnson & Siegler (1998) define conceptual knowledge as the understanding of principles and of relations between pieces of knowledge that are needed to solve novel tasks. They define procedural knowledge as the step-by-step actions (algorithms) efficient solving of routine problem-solving tasks. Many other researchers have addressed this distinction (e.g., Hiebert, 1986; Lesh & Landau, 1983; Ma, 1999; Starr, 2000) and there has been considerable debate about which kind of knowledge comes first developmentally and which kind should be instructed first. Some advocate that students learn concepts first and should use that knowledge to generate and select procedures (e.g., Gelman & Williams, 1998; Hiebert & Wearne, 1996). Others advocate that students learn procedures first and then should extract domain concepts from that experience (e.g., Hiebert & Wearne, 1996; Siegler, 1991). It may well be that different orderings are appropriate for different mathematical ideas. More importantly, it may be better to focus on how instruction can integrate the two in an iterative process. In such an approach, increases in one type of knowledge may lead to increases in the other type, which leads to further increases in the first (Rittle-Johnson & Alibali, 1999).

While many will acknowledge the effectiveness of Cognitive Tutors for procedural knowledge acquisition, the question arises about whether they are effective in supporting student acquisition of conceptual knowledge. Our work on Cognitive Tutor Math 6 has attempted to address this question (Rittle-Johnson & Koedinger, 2001; 2002).

### **Using the Bridging Principles in the Design of Cognitive Tutor Math 6**

#### **Course Overview**

We started work on the middle school text and software in the fall of 1999. In 2001-2002 school year the 6<sup>th</sup> grade course included 9 units of text and 36 units of software, summarized in Table 3. To illustrate the use of the principles, I will focus on the algebra and rational number strands running through the curriculum.

**Table 3.** Cognitive Tutor Math 6 Course Content—2001-02 School Year

| Textbook Units  | Tutor Units  | Strands                      |
|---|--|------------------------------|
| 1. Finding Patterns & Writing Rules                             | Algebraic Expression Generation, Expression Evaluation, Picture Algebra                                    | Algebra                      |
| 2. Grounding Place Value in Measurement                         | Decimal Number Line, Decimal Place Value, Decimal Addition & Subtraction                                   | Number                       |
| 3. Grounding Decimals in Area & Perimeter                       | Area & Perimeter with Decimals, Picture Algebra with Multiplication  | Number<br>Geometry           |
| 4. Understanding Division                                       | Expr Gen with Div, Compatible Numbers, Simplifying Div, Decimal Div with Area                              | Number<br>Algebra            |
| 5. Understanding Fractions, Equivalence, Addition & Subtraction | Fraction Concept, Proportional Reasoning, Probability, Fraction Arithmetic, Picture Algebra with Fractions | Number<br>Data & Probability |
| 6. Factors & Multiples  | Common Factors, Common Multiples, Scaling, Proportionality with Factors & Multiples                        | Number                       |
| 7. Fraction Multiplication & Division                           | Fraction Mult with Area, Picture Division, Fraction Mult & Div with Area                                   | Number<br>Geometry           |
| 8. Data Analysis  | Simple Histogram & Central Tendency  | Data                         |
| 9. Properties of Angles & Triangles                             | Sorting & Defining, Drawing, Discovering Properties, Angle Solving, Similar Triangles                      | Geometry                     |

**Emphasixing the need for content-relevant data.**

Instructional principles are true or useful only to the extent that the application of them is guided by content-relevant data. Our research related to the Situation-Abstraction principle provides an example. Table 4 illustrates different content areas in middle school math where we compared concrete story problem situations with abstract context-free problems. The table shows 6<sup>th</sup> graders' average percent correct on multiple

pre-test items in each category. In three of the areas, the problem situation consistently facilitates performance significantly above the abstract problem. These are decimal place value and decimal arithmetic (Rittle-Johnson & Koedinger, 2002) and fraction addition (Rittle-Johnson & Koedinger, 2001a). In data analysis (cf., Baker, Corbett, & Koedinger, 2001), the situation facilitated performance on a global interpretation task, but not on a local interpretation task. In the area of factors and multiples, the situation reduced performance.

Application of the Situation-Abstraction principle may not be effective for concepts and procedures related to factors and multiples unless situations can be found that are easier to understand than abstract problems. While one might still want to use such a problem situation as motivation for learning, given this data, it does not appear that such a situation will provide a student with easier or more direct access to understanding.

### **Examples from the Algebra Strand of Cognitive Tutor Math 6**

Unit 1 of the 6<sup>th</sup> grade curriculum is “Finding Patterns and Writing Rules”. The curriculum starts with a pre-algebra unit because it provides a good introduction to pattern finding, induction, and explaining patterns in general terms. This unit thus sets a tone for the rest of the school year where students will engage in pattern finding and rule discovery to gain deeper access into new concepts.

#### **Pattern induction and rule writing lessons illustrating Situation-Abstraction and Action-Generalization.**

Figure 1 shows a text sample from the first lesson in Unit 1, which is intended as a fun opening activity. Students engage in both a simple pattern discovery, find the minimum number of sections (pieces of cake) for  $N$  cuts ( $N+1$ ), and a difficult pattern discovery, find the maximum number of sections for  $N$  cuts (left to reader!). Students achieve various levels of success from finding correct section values for small  $N$ 's, through finding how the section values increase going down in the table (i.e., the “ $y$  differences”), to stating a rule for computing the sections given the cuts (i.e., the function). In our pilot classes, most 6<sup>th</sup> graders find the pattern of  $y$  differences for both minimum and maximum, and find and state the function for the minimum but not the maximum. When students do state a rule, it is usually in words (“just add 1 to the cuts”) and possibly including an instance (“say the cuts is 12, then one more is the sections”). In later lessons, students work through of a series of scaffolded situations (starting with single operator addition and going to combinations of two operators) to improve their ability to find patterns and to read and write verbal rules and algebraic expressions (see Figure 2).

Rule writing is also practiced in the tutor. The Algebraic Expression Generation tutor unit (see Figure 3) is similar to early lessons in the Algebra Cognitive Tutor. Following the Action-Generalization principle and the results of the parametric study

**Table 4.** Comparisons of Situational and Abstract Problems in Five Content Areas

|           | Decimal place value   | Decimal arith   | Fraction addition   | Data interp-global   |
|-----------|---|---|---|--|
| Situation | Show 5 different ways that you can give Ben \$4.07. [A place value table was provided to scaffold answers, but is not shown here] | You had \$8.72. Your grandmother gave you \$25 for your birthday. How much money do you have now? | Mrs. Jules bought each of her children a chocolate bar. Jarren ate 1/4 of a chocolate bar and Alicia ate 1/5 of a chocolate bar. How much of a chocolate bar did they eat altogether? | [2 scatterplots given]<br>Do students sell more boxes of Candy Bars or Cookies as the months pass? |
| % Correct | 61%   | 65%   | 32%   | 62%  |
| Abstract  | List 5 different ways to show the amount 4.07. [Place value table given.]   | Add: 8.72 + 25  | Add: 1/4 + 1/5  | [Scatterplots given] Are there more Moops per Zog in the Left graph or the Right graph?            |
| % Correct | 20%   | 35%   | 22%   | 48%  |

|           | Data interpretation-local   | Factors & Multiples  |
|-----------|---|--|
| Situation | [Scatterplot given] When 9 players from Anchoville were present, how many pizzas got eaten? | You work at a candy store. Your boss has asked you to figure out the different ways she could package the jelly beans and chocolate eggs, and she wants to know all the possible ways. If there are 64 jelly beans and 40 chocolate eggs and she wants each package to be the same, what are the different numbers of packages you could make? |
| % Correct | 64%   | 20%  |
| Abstract  | [Scatterplot given] In the Left graph, when there were 9 Pooks, how many Feeeps were there? | The common factors of 64 & 40 are:   |
| % Correct | 65%   | 37%  |

To celebrate the start of sixth grade, your class is going to have a party. They are going to buy a rectangular sheet cake. The cake needs to be sliced into pieces.

### Situation 1

Your job is to get the minimum number of pieces from each cut. All the cuts must be a straight line and must start and end on a side.

Complete the chart as you finish each cake. Don't be timid; draw extra rectangles if you need them.

| Number of cuts | Minimum number of sections |
|----------------|----------------------------|
| 1              | 2                          |
| 2              |                            |
| 3              |                            |
|                |                            |

Below are two examples of single cut cakes that are iced. Notice that the sections do not need to be even, just be certain that the lines are straight.

Figure 1. Text excerpt from lesson 1.1 in the 2001-02 version of Cognitive Tutor Math 6.

described above, students are first asked to solve for instances (rows 1 and 2 in Figure 3) before writing a general expression (final row). A major difference in the 6<sup>th</sup> grade tutor is the addition of the “Show Your Work” column. Having students move from instances to the algebraic expression is consistent with the notion of algebra as a generalization of arithmetic (e.g., Bednarz, Kieran, & Lee, 1996). Much to our surprise, however, we discovered that this generalization step is not the difficult one for students. In two studies reported on and referenced in Heffernan & Koedinger (1998), we found that students were not much worse at writing a general expression for story problems (49% correct) like “ $X * 2.0 - 1.25$ ” for the problem in Figure 3 than writing an instance-based expression (53%) like “ $5 * 2.0 - 1.25$ ”. However, writing either kind of expression was significantly more difficult than finding a numeric solution like 8.75 for the same story problems. In other words, it is the explanation step, going from “doing with an instance” to “explaining with an instance”, that is particularly difficult for students. Speaking in terms of students’ learning difficulties, one might say that algebra is the “explanation of arithmetic” rather than the “generalization of arithmetic”.

As indicated above, the Situation-Abstraction principle is at work in multiple places in the curriculum. Some problem situations are more authentic to real world concerns, while others, like the Cake and Marble Machine problems, are more playful. How well individual situations work either in terms of motivating students or making ideas more accessible are open questions. The process of generating problem

**Situation 3** Carol, feeling confident that she could break any code, went to the Marvelous Marble Machine. Unlike the computer code maker, the Marvelous Marble Machine uses two operators to compute its secret number.

The Marble Machine will take ordinary marbles and replace them with even more beautiful colored marbles. Of course there is a catch! You must break the code in order to keep your marbles. If you cannot break the code, you will lose your marbles.

The following table shows how many colorful marbles you will get when you insert ordinary marbles. Help Carol break the code.

| Ordinary Marbles | Colorful Marbles |
|------------------|------------------|
| 2                | 10               |
| 3                | 14               |
| 6                | 26               |
| 9                | 38               |

$$\begin{aligned}
 2 \times 4 + 2 \\
 3 \times 4 + 2 \\
 6 \times 4 + 2 \\
 9 \times 4 + 2 \\
 125 \times 4 + 2
 \end{aligned}$$

- a) How do you get from 2 ordinary to 10 colorful marbles?
- b) Does this same procedure work from 3 ordinary marbles to 14 colorful marbles? (If not try another possibility for the previous question)

Figure 2. Text excerpt showing an example pattern finding activity with student work.

situations is primarily an art at this point, but the process of evaluating problem situations (what situations are more accessible or motivating and why) could be more of a science than it is now.

A key premise of the algebra strand is that it will be pedagogically more effective if students first learn the syntax and semantics of the algebra language by writing and reading it before learning to use this language in problem solving. While writing and reading algebraic expressions is a regular activity throughout the 6<sup>th</sup> grade curriculum, little emphasis is placed on using algebraic expressions in problem solving. Students frequently engage in algebraic problem solving, but it is supported using strategies other than equation solving. One such strategy involves the use of pictures as I describe in the next section.

### Picture Algebra lessons illustrating Visual-Verbal and Conceptual-Procedural.

Figure 4 shows our initial instruction of Picture Algebra from Lesson 1.9 of the 2001-02 version of the text and Figure 5 shows an image from the associated tutor unit. This strategy is a variation of strategies used in Asian curricula (e.g., Singapore

**scenario**

**Problem**

You went to the grocery store to buy bottles of the new green colored ketchup. Each bottle costs \$2.00 and you had a coupon of \$1.25 off your grocery bill.

(1) If you bought 2 bottles, how much money would you owe?

(2) If you bought 5 bottles, how much money would you owe?

In the row labeled "Formula", define a variable for the number of bottles and use that variable to write an expression that will allow you to calculate the money you owe.

Problem FUNCTION-GEN-KETCH-UP

---

**worksheet**

|         | Number of bottles | Amount of money you owe | Show Your Work        |
|---------|-------------------|-------------------------|-----------------------|
| Unit    | bottles           | dollars                 | N/A                   |
| 1       | 2                 | 2.75                    | $2 \times 2.0 - 1.25$ |
| 2       | 5                 | 8.75                    | $5 \times 2.0 - 1.25$ |
| Formula | $x$               | $x \times 2.0 - 1.25$   | —                     |

Figure 3. Image of Algebraic Expression Generation tutor unit with "Show your work" column.

Ministry of Education, 1999). It also bears similarity with picture strategies used in Math in Context. As one point of evidence for the power of this strategy, we have observed 6<sup>th</sup> graders using it to successfully solve problems that many older students (who usually attempt an equation solving strategy) fail to solve (Koedinger & Terao, 2002). Whereas 7<sup>th</sup> graders in a sample from Bednarz & Janvier (1996, p. 120) were only 5% correct on the problem below, 6<sup>th</sup> graders in a Cognitive Tutor class were 26% correct on this problem after Picture Algebra instruction.

The use of Picture Algebra is consistent with the Visual-Verbal principle. This strategy integrates students' visual sense of quantity size with their prior verbal and symbolic skills for performing arithmetic operations. By drawing boxes of appropriate sizes, labeling, and performing associating arithmetic operations, students construct

**Situation 1**

Suppose you want to buy a CD and magazine. The two cost \$17 together. If the CD costs \$9 more than the magazine, how much does the magazine cost?

One way to view this problem is to draw a picture to represent the objects. Be sure to label the drawings

If you remove the extra \$9 from the total cost of \$17, what will be left?

*Figure 4.* Text excerpt showing initial instruction of Picture Algebra from Lesson 1.9 of the 2001-02 version.

an integrated representation that may assist them in developing a “central conceptual structure” for algebraic reasoning.

Picture Algebra is also consistent with the Conceptual-Procedural principle. It is meant to help students acquire a conceptual understanding of key algebraic ideas. One key idea regards transformations that maintain equality, for instance, subtracting 9 from the bars on the left and the total (cf., Rittle-Johnson & Alibali, 1999). A second regards methods for recombining constraints on unknowns, for instance, seeing that the equal parts of the unknowns can be combined (analogous to transforming “ $x + (x + 9)$ ” into “ $2x + 9$ ”). Currently, instruction that emphasizes integration of this conceptual approach with equation solving procedures is being left for 7<sup>th</sup> and 8<sup>th</sup> grade in our curricular program. It is a good question whether or not saving the integration for later is a violation of the Conceptual-Procedural principle and, separately, whether or not earlier integration would help learning.

### **Examples from the Rational Number Strand of Cognitive Tutor Math 6**

Rational numbers are a cornerstone of advanced mathematics and a major stumbling block for many children. Multiple units in the curriculum, especially Units 2-7, address number knowledge and rational numbers in particular.

#### **Decimal place value and arithmetic lessons illustrating Situation-Abstraction and Conceptual-Procedural.**

In text unit 2 and associated Tutor units, we targeted decimal number understanding with a particular emphasis on combining the Situation-Abstraction and the Conceptual-Procedural principles. The Conceptual-Procedural principle was employed

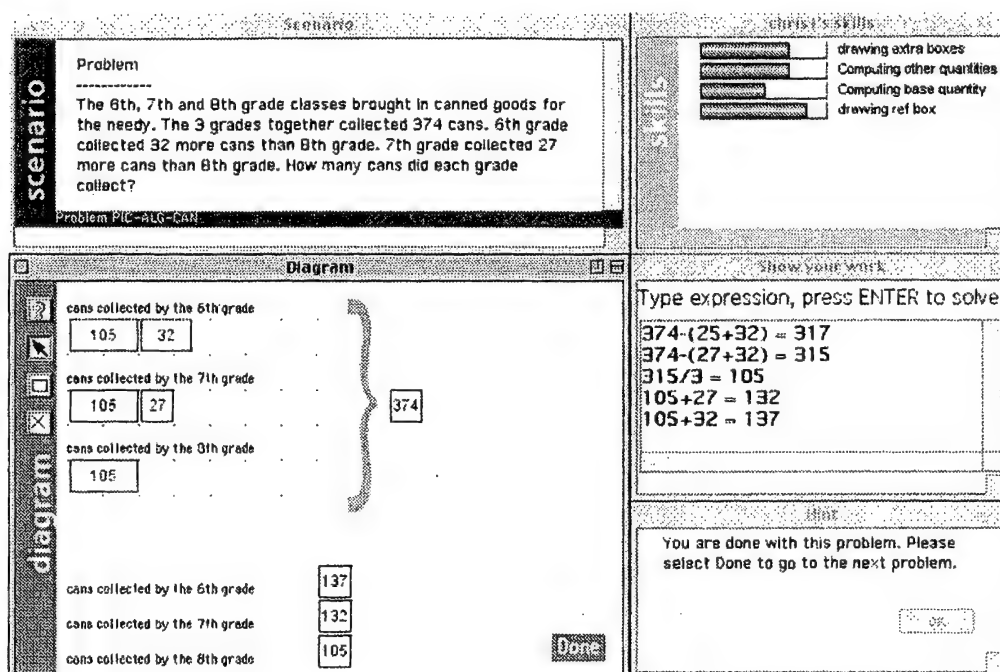

Figure 5. Image of problem from Picture Algebra tutor unit. In the Diagram window, students draw boxes of appropriate size and label them (the text is given but the boxes are not). In the "Show your work" window, students must justify their answers. The tutor monitors each step and provides context-sensitive hints only as needed (by clicking on the ? icon).

through the integration of place value concepts and decimal addition and subtraction procedures. The curriculum emphasizes the alignment and adding of equivalent place values (add ones to ones, tenths to tenths, etc.) as a rationale for the procedure of aligning the decimal point. The Situation-Abstraction principle was employed through the initial use of situations involving money quantities before other non-money and abstract situations. Money contexts appear to dramatically reduce decimal alignment errors in arithmetic, as we saw in Koedinger & Nathan (in press) and in the difficulty factors comparison illustrated above. The two principles combine well here as the key abstract conceptual-procedural link, do not add different place values, has an easier to understand analog in the concrete money situation, do not add dollars and cents. In other words, add ones to ones and tenths to tenths is analogous to add dollars to dollars and dimes to dimes. Rittle-Johnson & Koedinger (2002) report on an experiment demonstrating the value of iterating between conceptual and procedural lessons, first within the familiar money situations and then more abstractly.

### Fraction concept and addition lessons illustrating Visual-Verbal and Action-Generalization.

Learning to add and subtract fractions is particularly difficult for students as indicated by the fact that incorrect procedures persist into high school and reflect basic misunderstandings of fractions (e.g., Kouba, Carpenter, & Swafford, 1989). The most common error children make is to add the numerators and denominators (e.g.,  $1/4 + 1/5 = 2/9$ ), which violates basic part-whole concepts and can lead an answer that is smaller than either addend. In Rittle-Johnson & Koedinger (2001) we explored whether presenting problems with pictures or within a situational context would enhance performance and, in particular, provide a source for sense-making that would reduce this common error. Indeed, on a pre-test given to 6<sup>th</sup> graders, students performed better when given a problems with pictures (37%) or within a situation (32%; see Table 4) than when given an abstract number sentence (22%). In particular, the combine numerator and denominator error, while still common prior to instruction, was significantly lower for both pictures (38%) and situations (39%) than for the number sentence (48%). Relevant prior knowledge appears to be elicited by pictures and situations and it appears that, even without instruction, some students use such knowledge for sense making.

In addition to indicating room for improvement among 6<sup>th</sup> graders, these results suggest promise for applying the Situation-Abstraction and Visual-Verbal principles to fraction concepts and fraction arithmetic. Lesson 5.10 addressed fraction addition, but it is important to first review what ideas were addressed earlier in the unit along the developmental corridor leading to fraction addition. Students are encouraged to discover multiple ways of expressing fractions of equivalent value. Following the Visual-Verbal principle, the concept of fraction equivalence (and comparison) is supported through

Figure 6. Student using her fraction strip to measure the result of combining the  $1/3$  of the weekly goal collected on Monday and the  $1/6$  of the weekly goal on Tuesday. She measures the result to be  $1/2$ .

measurement activities and pictorial representations—fraction bars, number lines, and analogous representations in the Cognitive Tutor software. As part of the measurement activities, students create a fraction ruler that is a whole unit in length and labeled with multiple fractions. This ruler is both a frequently used tool and a concrete reminder of fraction equivalence as many positions on the ruler are labeled with multiple fractions (e.g.,  $1/4$  and  $2/8$ ).

In lesson 5.1, students begin an activity involving a fund raising effort at the middle school (see Figure 6). (Note: “Penny Wars” is the name of an annual fundraiser at a local school, but we are changing the name in the text to “Penny Race”.) The fund-raiser has a goal for the week and students record in a bar chart the fractional progress toward that goal for each grade on each day. As illustrated in Figure 6, students use their fraction ruler to measure the total of the 7<sup>th</sup> graders’ penny collection on Monday,  $1/3$  of the goal, and on Tuesday,  $1/6$  of the goal. The measurement shows that the 7<sup>th</sup> graders are now  $1/2$  of the way to their goal.

At this point, the Action-Generalization principle is employed. Students record such measurements (actions) and instances of associated arithmetic facts (e.g.,  $1/3 + 1/6 = 1/2$ ). As shown in Figure 7, students revisit these facts in lesson 5.10 and have a discussion about how to add fractions. Why is it that  $1/3 + 1/6$  is  $1/2$ ? The prior emphasis on fraction equivalence and its reification on the fraction ruler has the consequence that it is not a difficult leap for students to think of  $1/3$  as  $2/6$ . Thus, they are in position to recognize that they already know how to add  $2/6 + 1/6$  (like fraction addition is a topic prior to 6<sup>th</sup> grade). Having begun to recognize a pattern, students are asked to experiment with their procedure idea on other arithmetic facts. Once their

### Situation 2 – Adding Fractions with Unlike Denominators

Look back at the penny war results for Tuesday (page 7). The sixth grade collected  $1/4$  of its weekly goal on Monday, and  $1/8$  of its goal on Tuesday. The total for the week was measured at  $3/8$  of the total goal. The diagram and number line display the problem and the answer.

Figure 7. Revisiting the fraction addition facts determined by physical arithmetic to use as a basis for finding patterns and writing a fraction addition procedure.

Complete the example for adding  $\frac{1}{4} + \frac{1}{8}$  and use the example to write your own steps for adding fractions with unlike denominators.

$$\begin{array}{r}
 \frac{1}{4} \times \frac{2}{2} = \frac{2}{8} \\
 + \frac{1}{8} \times \frac{1}{1} = \frac{1}{8} \\
 \hline
 = \frac{3}{8}
 \end{array}$$

My steps used to add fractions:

- 1.) Find a common denominator.
- 2.) Multiply the denominator and the numerator by the number that will make them common.
- 3.) Add the numbers.
- 4.) check and place answer in simplest form.

Figure 8. A student's procedure for addition of unlike fractions.

procedure seems to be working they write it down. Figure 8 shows one student's written procedure.

Note the progression of activities in this the application of the Action-Generalization principle. First students are "doing with instances" by using measurement to physically find fraction sums. Next, students are "doing with a generalization" by attempting to test an idea for a fraction addition procedure (which is not yet articulated) with new instances. Finally students "explain with a generalization" by writing a procedure for fraction addition in their own words. This approach is applied for other concepts in the curriculum.

### An Initial Full Course Evaluation of Cognitive Tutor Math 6

We began research and development of Cognitive Tutor Math 6 in 1999 and immediately began testing in classrooms. In the 2000-2001 school year, a complete alpha version of Cognitive Tutor Math 6 was used at two Pittsburgh-area schools. To evaluate the effect of the course on raising student achievement, we contrasted end-of-course performance of students in Cognitive Tutor classes with students in schools with comparable demographics. Two types of assessments were used, a "Standard-

ized Skills” test made up of selected test items from State and National standardized tests and a “Problem Solving and Concepts” test that we developed to assess students’ problem solving abilities and conceptual understanding. The test items were selected or created to be challenging and with the goal that average performance would not be far from 50%.

Table 5 summarizes students’ average percent correct on the two assessments in Cognitive Tutor and comparison classes in two school districts. All four differences between Cognitive Tutor and comparison student performance are statistically reliable.

It was not feasible to randomly assign students or teachers to tutor versus comparison classes given the logistics of agreements with the districts. Thus, there is some chance that the differences are due to other factors. However, it is encouraging that students in Cognitive Tutor classes consistently outperformed students in comparison classes on both assessments and at both schools.

### Conclusions and Future Work

Cognitive Tutor courses have achieved considerable success both in terms of raising student achievement and in reaching large numbers of students. So have other research-based mathematics curricula. Nevertheless, it is critical we remain humble about our theories and beliefs about appropriate and effective mathematics instruction. There is still plenty of room for novel ideas in mathematics instruction. Moreover, there is even more room for firm evidence that existing ideas are effective in increasing student learning and do so in ways that can scale up to widespread cost-effective use. A particular gap exists between theories of general cognitive function and theories of mathematics content. We need theories and principles in this intermediate terrain that provide pedagogical leverage. Ma’s (1999) work and the more general effort to characterize pedagogical content knowledge (e.g., Shulman, 1986) are extremely valuable toward filling the gap, but better still if such work makes contact with theories of general cognitive function. From the psychological side, efforts to characterize general learning and instructional principles (Bransford, et al., 1999) are also useful. However, better still if we had more specific principles and associated methods that make contact with specific pedagogical content issues.

**Table 5.** Results of an Initial Full Course Evaluation of Cognitive Tutor Math 6

| School District | Test               | Cognitive Tutor | Comparison Classes | T-test p-value |
|-----------------|--------------------|-----------------|--------------------|----------------|
| District A      | Standardized       | 63% (N=47)      | 54% (N=50)         | < 0.001        |
|                 | Solving & Concepts | 50% (N=48)      | 41% (N=48)         | 0.007          |
| District B      | Standardized       | 71% (N=37)      | 64% (N=132)        | 0.046          |
|                 | Solving & Concepts | 69% (N=38)      | 62% (N=116)        | 0.045          |

I have made some, I hope humble, attempts to articulate some principles within this intermediate terrain: Situation-Abstraction, Action-Generalization, Visual-Verbal, and Conceptual-Procedural. They bear considerable similarity to a number of other approaches that I am aware of and probably many more that I am not. My point is not to argue that these principles are particularly new. Nor is it to argue that I have provided firm proof for any them. Indeed, I think attempts to “prove” such principles are premature and perhaps even wrong-headed. I do suggest that we need to accumulate evidence that indicates guidelines for when and how to apply principles like these. I also suggest that such principles cannot be applied purely analytically – they require associated empirical facts, for instance, about whether particular situations or visualizations ease understanding.

This paper presented an overview of our new Cognitive Tutor Math 6 course, some samples of text and tutor activities within it, and some early evaluation data that seems to indicate that students may be learning more from this course than alternatives. I actually have not said much about the unique features of Cognitive Tutors, but have written about them elsewhere. Perhaps the most important feature is the capability to approximate the kind of moment-by-moment individualized assistance that a good human tutor can provide. The classroom teacher is a critical component in Cognitive Tutor classes, but when teachers are in the computer lab they have the support of what is, in effect, an automated teacher’s aid for every student. This extra support allows them to give more individualized attention to the students who most need it (Schofield, Evans-Rhodes, & Huber, 1990; Wertheimer, 1990). Such automated support is not possible without theory-based analyses of learners and learning.

Looking forward, I would like to see mathematics educators and cognitive scientists explore the feasibility and advisability of a large program of research, on the order of the human genome project, to identify and catalog the knowledge structures or cognitive objects that underlie mathematical thinking and learning. This knowledge base would help drive new instructional innovations and provide for a rich cause theory of how, when, & why they may work. Like the human genome project, such an ambitious program would yield major applied and basic research outcomes.

# LINKING RESEARCH AND PRACTICE: KNOWLEDGE TRANSFER OR KNOWLEDGE CREATION?

Dylan Wiliam  
King's College London  
dylan.wiliam@kcl.ac.uk

In this paper, it is argued that the failure of educational research to impact on practice stems from a failure to understand the nature of expertise in teaching, and that traditional models of knowledge *transfer* can only be effective for those at a relatively limited level of competence. Instead, it is suggested that teachers need to be involved, collaboratively, with researchers in a joint process of knowledge *creation*. In the King's-Medway-Oxfordshire Formative Assessment Project (KMOFAP) a group of 24 secondary school teachers (grades 6 to 12) of mathematics and science were supported in developing action plans of how they wanted to develop their classroom assessment practice with a single class, through a series of four day-long workshops, and by observations of their teaching. Comparison with local controls (established on a case-by-case basis for each teacher) on curriculum-based tests, showed an average effect size of +0.32.

## Introduction

Although the amount of money spent on educational research in most countries over the last hundred or so years has only been a tiny fraction of the expenditure on education (ranging from one-third of a percent to one percent in most developed countries in recent years) a large amount of money has certainly been spent on educational research, and yet its impact is very hard to discern.

The failure of educational research to have any real impact on educational practice in general, and on mathematics education in particular, has been lamented for many years. Today, there are, it seems, two broad strands of criticism of research in education. The first is that educational research is unnecessary. This manifests itself either in a belief that expert practitioners already know 'what works' in mathematics classrooms and so novice mathematics teachers can learn all they need to know by watching experienced teachers, or that pedagogical practice will always be weak, and that the solution lies in prescribing curricula and teaching methods in 'teacher-proof' schemes.

The second strand regards educational research as necessary, but of poor quality. Too often, it is said, educational research produces results that are ambiguous or contradictory, perhaps best summed up by Robert Kennedy's furious reaction to the ambiguous evaluation of the impact of additional money provided for the education of socioeconomically disadvantaged students: "Do you mean that you spent a billion dollars and you don't know whether they can read or not?" (Lagemann, 2000, p. 202). On those few occasions when research does produce unambiguous results, these are generally felt to tell us what we already knew. The lament continues: If educational

researchers could only agree how to go about research properly, then educational research could join the elite club of 'hard' sciences producing reliable knowledge (these people have in the past rather unkindly been described as suffering from 'physics envy').

In this paper, I want to suggest is that by its very nature, by the nature of the things it studies, educational research cannot produce 'reliable knowledge' in the sense that Physics—the paradigm case—has done. Modern Physics may be complex, but its successes have been secured because the things it studies, complex as they are, are actually rather simple compared to educational processes. In education, the pursuit of Grand Unified Theories that provide reliable descriptions of what to do in every situation is doomed to fail. Instead, I want to argue that educational research should be about the pursuit of 'practical wisdom' about how educational processes can be improved, and a necessary corollary of this will be that educational research cannot be done 'on' teachers, but only with them, and that this should be not a process of getting teachers to do what we want them to do (co-operation) but of creating knowledge, with teachers (collaboration).

In doing so, I hope to show that such a shift does not entail a down-grading of educational research to a pseudo science, but that, as was first argued by Aristotle the pursuit of practical wisdom is actually a higher-order goal than the pursuit of pure knowledge. The remainder of the paper then goes on to describe how these ideas about collaborative research were put into practice with a group of teachers in the King's-Medway-Oxfordshire Formative Assessment Project (KMOFAP).

### **The (Troubling) History of Educational Research**

The history of educational research can be viewed as a search for disciplinary foundations. At the beginning of the last century, educational research, to the extent that it existed at all, was either historical or an aspect of philosophy. One of the earliest attempts to use empirical methods in educational research was the 'School Survey' movement in the United States. Beginning around 1910 this movement sought to gather 'objective evidence' about factors influencing the educational progress of school students. However, due to the sheer diversity of the United States education system, with over 100,000 school districts each free to determine its own education policy, there was little agreement about the purpose or scope of education, and meaningful comparisons of educational outputs was almost impossible.

In *An Elusive Science* (whose subtitle is the title of this section) Ellen Condcliffe Lagemann (2000) shows that the search for ways of producing high-quality research in education has been, in effect, a search for secure disciplinary foundations for the production of reliable knowledge. At first, philosophy and history provided those foundations but, around the turn of the century, these were supplanted by psychology, which dominates to the present day, although since the 1970s sociology and social anthropology have also been influential.

Lagemann argues that the failure of educational research to deliver what has been wanted has arisen from three main causes—the isolation and low status of educational research in the academy; its tendency to focus too narrowly on particular aspects of education rather than looking at education systems; and the weak governance and regulation of educational research. These three causes are of course intimately entwined.

In the United States, teaching had been regarded as ‘women’s work’ since early in the nineteenth century, so that educational research was accorded low status by association. Lagemann also points out that being an applied subject served to marginalia education within the academic mainstream. No doubt partly in an attempt to raise its status, educational research attempted to emulate the hard sciences through the quantification of educational processes, which of course entailed focusing on those aspects of education that could be easily quantified. And while most teachers were female, most school supervisors and district administrators were male, so that the emerging field of educational research emphasized educational administration almost from the outset.

This lack of agreement about not just how to undertake educational research, but also what should be researched continued to plague attempts to establish ‘what works’ in education over the next half-century, but Lagemann’s history closes with an ironic twist. In the final quarter of the last century, educational research finally began to get on the right track with two key realizations. Firstly, the complexity of educational settings requires that insights from all of the ‘foundation disciplines’ (and not just one) are required to make progress in educational improvement. Secondly, it slowly became clear that centre-periphery models of dissemination are simply ineffective in education. The result was a blossoming of multi-disciplinary research, involving teachers in real innovation and improvement. However, at the same time, it seems that the politicians gave up on educational research, and by 1991, federal funding for educational research in the USA stood at approximately one-third the level provided in 1971.

While Lagemann’s analysis is persuasive, I want to suggest here that the goal of educational research as a science is not just elusive, but impossible. This is in part a philosophical claim, but it is also in part an empirical claim. The phenomena that are studied in educational research are, in the first instance, far more complex than those that are studied by the ‘hard’ sciences—just imagine trying to set boundary conditions for the initial state of a typical mathematics classroom. However, in addition, it is important to realize the autonomy that individual students bring to lessons is not a problem with which physical sciences have to grapple. Bars of iron do not behave differently because someone has been testing them. Or more precisely, while bars of iron may behave differently depending on how they have been treated in the past (ie whether they have been annealed or subject to repeated stress and strain), we know what kinds of treatments matter, and we know how to find out in advance how the bar will perform under tests. Even those who believe that there is no such thing as free

will, and that all human behavior at time T1 is actually determined by the state of the system at T0 have to concede that it is too difficult to specify the starting conditions precisely enough to determine the outcome. Chaos theory, and, at a smaller scale, Heisenberg's uncertainty principle, renders Laplace's dream of being able to predict all behavior from initial conditions a non-starter.

### Expertise

There are also reasons to suspect that the nature of expertise in teaching is not reducible to the kinds of recipes used in the physical sciences. Flyvbjerg (2001) reports an experiment that was conducted on a group of paramedics (Klein & Klein, 1981). Six short video extracts of a person administering cardiopulmonary resuscitation (CPR) were shown to experienced paramedics, students being trained as paramedics, and people who taught life-saving techniques. They were then asked which of the six they would choose to resuscitate them if they needed CPR. Five of the six video extracts were of inexperienced trainees just learning CPR while the sixth was a highly experienced paramedic. Of the experienced paramedics, 90% chose the experienced paramedic, while only 50% of the students did so. However, only 30% of the instructors chose the experienced paramedic.

Flyvbjerg argues that we can understand this apparently paradoxical result by considering the five levels of expertise in learning proposed by Dreyfus and Dreyfus (1986). At the *novice* level, the individual is guided by rules that are applied irrespective of context. The novice teacher tends to try to apply the same sets of rules to all the classes they teach. The *advanced beginner* begins to take situationally-specific factors into account, and personal experience is often relied on more than context-independent rules. However, as experience accumulates, the number of recognizable elements or 'chunks' increases, and threatens to overwhelm the individual. For example, the need for the school teacher to attend to the learning needs of her or his students, controlling the behavior of some, while also trying to make sure that they interact as much with female and male students, can lead to a feeling of 'plate spinning'—dashing from one imperative to the next to try to attend to all. The *competent performer* is characterized by performance in which conflicting priorities are resolved through the use of strategies, usually derived from conscious problem-solving behavior. In contrast, the *proficient performer* acts quickly and intuitively often doing the 'right thing' without conscious awareness. In this context, it is important to realize that 'intuition' is used here not as some irrational prejudice, but rather as the result of the sedimentation and synthesis of vast amounts of experience. Finally, in the *expert*, the ability to act quickly and intuitively, in a range of contexts and settings, is unified into a 'feeling' of the right thing to do. The use of an emotive term—'feeling'—here is not coincidental. Experts 'feel' the best course of action, not just with their mind, but in their whole body. Expertise is therefore not the culmination of rationality, but rather transcends it.

Expertise involves going beyond what can be done through rationality, not irrational, but meta-rational (i.e. beyond rationality).

Therefore, Flyvbjerg argues, it appears that the paramedic trainers identified the trained paramedics less successfully because they looked for paramedics who followed the rules that they themselves taught. In other words, they were looking for those at the level of competent performers, rather than proficient performers or experts. If we accept that the classification proposed by Dreyfus and Dreyfus also applies to teaching, then it seems likely that the failure of educational research to impact on educational practice stems from a similar limitation.

The kinds of prescriptions given by educational research to practice have been in the form of generalized principles, that may often, even usually, be right, but are sometimes just plain wrong. The expert can see that a particular recipe is inappropriate in some circumstances, although because their response is intuitive, may not be able to discern the reason why. What the practitioner learns is that the findings of educational research are not a valid guide to action.

But research findings also run foul of the opposite problem—that of insufficient specificity. Many teachers complain that the findings from research produce only bland platitudes that are insufficiently contextualized to be used in guiding action in practice. Put simply, research findings underdetermine action.

### **Knowledge Transfer and Knowledge Creation**

If we accept that the prime (although not the only) purpose of educational research is the improvement of educational processes, then research findings must be taken up by teachers and incorporated into their practice. There are other ways that educational research might influence practice—through the improvement of textbooks for example—but without some change in those who use them, innovations are unlikely to have much effect. In the past, this process has been called dissemination, and is now more often called knowledge transfer—both interesting metaphors, suggesting that all that needs to be done is to inform practitioners about the latest findings and they will be used. If expertise transcends rationality, as I have argued above, however, then the process of knowledge transfer cannot be one of providing instructions to novices, advanced beginners, or competent performers in the hope that they will get better. Rather what is needed is an acknowledgement that what teachers do in ‘taking on’ research is not a more or less passive adoption of some good ideas from someone else, but an active process of knowledge creation:

Teachers will not take up attractive sounding ideas, albeit based on extensive research, if these are presented as general principles, which leave entirely to them the task of translating them into everyday practice—their classroom lives are too busy and too fragile for this to be possible for all but an outstanding few. What they need is a variety of living examples of implementation, by teachers with whom they can

identify and from whom they can both derive conviction and confidence that they can do better, and see concrete examples of what doing better means in practice. (Black & Wiliam, 1998b, pp. 15-16)

The different ways in which knowledge is transferred and created within organizations has been studied by Nonaka and Takeuchi (1995) who have proposed a simple framework for knowledge creation in organizations. In their model, there are four modes of knowledge conversion, depending on whether knowledge is converted to or from implicit or explicit knowledge (see figure 1).

The traditional kind of knowledge conversion practiced by educational researchers is what Nonaka and Takeuchi call *combination*. Knowledge in an explicit form is converted to more knowledge in explicit form. At the other extreme, *socialization* is their name for the process by which new practitioners become enculturated into new practices which are not known explicitly to those who are learning, nor to those from whom they are learning. Tacit knowledge becomes explicit knowledge through a process of *externalization*, and explicit knowledge becomes implicit by *internalization*. A learning cycle can then be set up in which knowledge is created, transformed, and circulated around an organization. Through *learning by doing* systemic knowledge becomes operationalized, which can then be *shared* with other practitioners. In dialogue with others conceptual knowledge is built up, which is then combined with that of others through networking. It was this knowledge cycle that we attempted to implement in the King's-Medway-Oxfordshire Formative Assessment Project (KMOFAP) funded initially by the Nuffield Foundation (as the *Developing Classroom Practice in Formative Assessment* project) and subsequently by the United States National Science Foundation through their support of our partnership with the Stanford CAPITAL project (NSF Grant REC-9909370)

### **Collaborating with Teachers: The KMOFAP Project**

Reviews of research by Natriello (1987) and Crooks (1988) and more recently by Black and Wiliam (1998a) had demonstrated that substantial learning gains are possible when teachers integrate assessment with classroom instruction. However, it is also clear from these reviews, and from other studies (see Black and Atkin 1996) that achieving this is by no means straightforward. As Black and Wiliam (1998b) point out:

Thus the improvement of formative assessment cannot be a simple matter. There is no 'quick fix' that can be added to existing practice with promise of rapid reward. On the contrary, if the substantial rewards of which the evidence holds out promise are to be secured, this will only come about if each teacher finds his or her own ways of incorporating the lessons and ideas that are set out above into her or his own patterns of classroom work. This can only happen relatively slowly, and through sustained programmes of professional development and support. This does not weaken the message here—indeed, it should be a sign of its authenticity, for lasting and fundamental

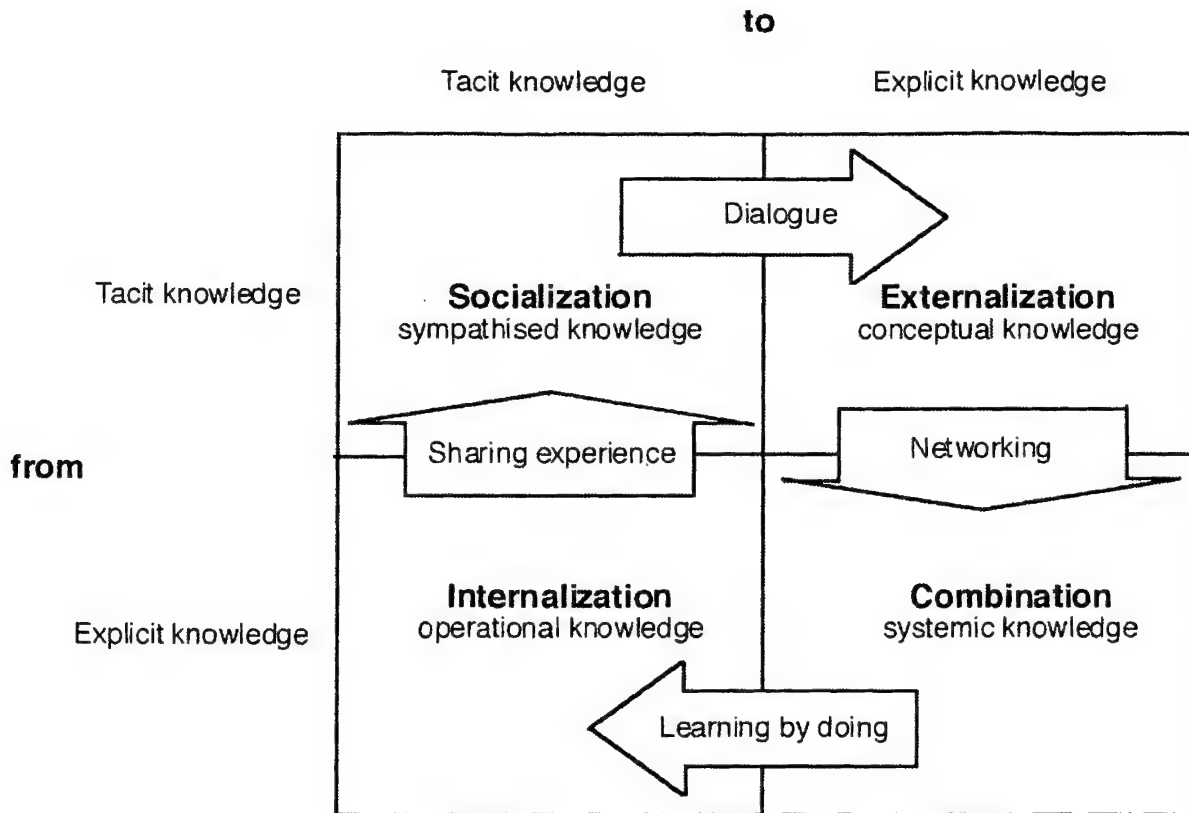

Figure 1. Four modes of knowledge conversion (after Nonaka & Tagueuchi, 1995).

improvements in teaching and learning can only happen in this way. (p. 15)

The challenge for us, then, was how could teachers be supported in incorporating formative assessment (or assessment for learning as it is sometimes called) into their classroom practice, not as a 'bolt on' series of tactics, but integrated into planning and teaching?

### The Research Strategy

The central tenet of the research project was that if the promise of formative assessment was to be realized, traditional research designs—in which teachers are 'told' what to do by researchers, for all the reasons discussed above—would not be appropriate. We therefore decided that we had to work in a genuinely collaborative way with a small group of teachers, beginning in the bottom left-hand corner of Nonaka and Takeuchi's model, by sharing with them our understanding of the research literature. We then invited the teachers to explore some of these ideas for themselves, by trying them out in their own classrooms (internalization). At first, they were hesitant. Although we told them that we did not have a clear plan for what they should do, the teachers did not believe this. They seemed to believe that we were operating with a perverted model of discovery learning in which we knew full well what we wanted

the teachers to do, but wouldn't tell them, because we wanted the teachers 'to discover it for themselves'. However, after a while, it became clear that there was no prescribed model of effective classroom action, and each teacher would need to find their own way of implementing the general principles of high-quality classroom assessment in their own classrooms. We then planned that they would share their experiences with other teachers in the group, and develop a common way of thinking about classroom assessment (socialization). Through extended dialogue, we hoped that they could then develop a common language of description (externalization) thus yielding findings that could be made explicit, so beginning another cycle (combination).

### **The Sample**

We began by selecting two school districts where we knew there was support from the authority for attempting to develop formative assessment, and, just as importantly, where there was an individual officer who could act as a link between the research team and the schools, thus providing a local contact for ad hoc support for the teachers. In this regard, we are very grateful to Sue Swaffield from Medway and Dorothy Kavanagh from Oxfordshire who, on behalf of their authorities, helped to create and nurture our links with the schools. Their involvement in both planning and delivering the formal inservice sessions, and their support 'on the ground' were invaluable, and it is certain that the project would not have been as successful without their contributions.

Having identified the two districts, we asked each district to select three schools that they felt would be suitable participants in the project. We were very clear that we were not looking for 'representative' or typical schools. From our experiences in curriculum development—for example in graded assessment (Brown, 1988)—we were aware that development is very different from implementation. What we needed were schools that had already begun to think about developing 'assessment for learning', so that with these teachers we could begin to produce the 'living examples' alluded to earlier to use in further dissemination.

Each district identified three schools that were interested in exploring further the possibility of their involvement, and the project directors visited each school with the officer from the school district to discuss the project with the principal and other members of the senior management team. All six schools identified agreed to be involved. Brief details of the six schools are shown in table 1.

In our original proposal to the Nuffield Foundation, we had proposed to work only with mathematics and science teachers, partly because of our greater expertise in these subjects, but also because we believed that the implications for assessment for learning were clearer in these areas. In order to avoid the possible dangers of isolation, our design called for two mathematics and two science teachers at each school to be involved.

**Table 1.** The Six Schools Involved in the Project

| School          | Abbreviation | Description |
|-----------------|--------------|-------------|
| Brownfields     | BF           | Boys        |
| Century Island  | CI           | Mixed       |
| Cornbury Estate | CE           | Mixed       |
| Riverside       | RS           | Mixed       |
| Two Bishops     | TB           | Mixed       |
| Waterford       | WF           | Girls       |

The choice of teachers was left to the school, and a variety of methods was used. In some schools, the principals nominated a faculty chair together with a relatively inexperienced teacher. In other schools, teachers appeared to be selected because, in the words of one head, "they could do with a bit of inset [professional development]". In the event while our schools were not designed to be representative, there was a considerable range of expertise and experience amongst the 24 teachers selected.

### **The Intervention**

The intervention had two main components:

- a) a series of half-day and one-day professional development days, during which teachers would be introduced to our view of the principles underlying formative assessment, and have a chance to develop their own plans;
- b) visits to the schools, during which the teachers would be observed teaching by project staff, and have an opportunity to discuss their ideas, and how they could be put into practice more effectively.

The pattern of professional development sessions is shown in table 2 (subsequent events were held as part of the NSF-funded work on the CAPITAL project, but the data reported here relate to the original project, from January 1999 to August 2000.

The key feature of the sessions was the development of action plans. Since we were aware from other studies that effective implementation of formative assessment requires teachers to re-negotiate the 'didactic contract' (Brousseau, 1984) that they had evolved with their students, we decided that implementing formative assessment would best be done at the beginning of a new school year. For the first six months of the project, therefore, we encouraged the teachers to experiment with some of the strategies and techniques suggested by the research, such as rich questioning, comment-only marking, sharing criteria with learners, and student peer- and self-assessment. Each teacher was then asked to draw up, and later to refine, an action plan specifying

**Table 2.** Pattern of Professional Development Events

| Inset | Held      |      | Format                   | Focus   |
|-------|-----------|------|--------------------------|---|
| A     | February  | 1999 | whole-day, London        | introduction  |
| B     | May       | 1999 | whole-day, London        | developing action plans   |
| C     | June      | 1999 | whole-day, London        | reviewing and revising action plans   |
|       | September | 1999 | half-day, district-based | reviewing and revising action plans   |
| D     | November  | 1999 | whole-day, London        | sharing experiences, refining action plans, planning  |
| E     | January   | 2000 | whole-day, London        | dissemination<br>research methods, dissemination, optional sessions including                         |
| F     | April     | 2000 | whole-day, London        | theories of learning<br>integrating learning goals with target setting and planning, writing          |

which aspects of formative assessment they wished to develop in their practice and to identify a focal class with whom these strategies would be introduced in September 1999. Although there was no inherent structure in these plans, the teachers being free to explore whatever they wished, we did find that they could be organized under the broad headings shown in table 3. In all the 24 teachers included a total of 102 activities in their action plans—an average of just over four each—and while there were a small number of cases of teachers of the same subject at the same school adopting common plans, there was no other clustering of teachers discernible. Inevitably the clear phases suggested by Nonaka and Takeuchi's model became increasingly blurred over the course of the project, with discussion frequently involving all four modes. While it has not been useful for analysis of the data arising from the project, nevertheless, we believe that the model provided a useful framework for shaping our initial interventions.

Most of the teachers' plans contained reference to two or three important areas in their teaching where they were seeking to increase their use of classroom assessment generally followed by details of strategies that would be used to make this happen. In almost all cases the plan was given in some detail, although many teachers used

**Table 3.** Frequencies of Activities in the Action Plans of 24 Teachers

| Category                       | Activity                          | Code   | Frequency |
|--------------------------------|-----------------------------------|--------|-----------|
| Questioning                    | Teacher questioning               | TO     | 11        |
|                                | Pupils writing questions          | PWQ    | 8         |
|                                | Existing assessment: pre-tests    | EAPT   | 4         |
|                                | Pupils asking questions           | PAQ    | 4         |
| Feedback                       | Comment-only marking              | COM    | 6         |
|                                | Existing assessment: re-timing    | EART   | 4         |
|                                | Group work: test review           | GWTR   | 4         |
| Sharing criteria with learners | Course work: marking criteria     | CWMC   | 5         |
|                                | Course work: examples             | CWEG   | 4         |
|                                | Start of lesson: making aim clear | SoLMAC | 4         |
|                                | Start of lesson: setting targets  | SoLST  | 1         |
|                                | End of lesson: teacher's review   | EoLTR  | 1         |
|                                | End of lesson: pupils' review     | EoLPR  | 4         |
|                                | Group work: explanation           | GWExp  | 2         |
|                                | Involving classroom assessment    | ICA    | 2         |
| Self-assessment                | Self-assessment: traffic lights   | SATL   | 11        |
|                                | Self-assessment: targets          | SAT    | 5         |
|                                | Group work: test review           | GWTS   | 6         |
|                                | Self-assessment: other            | SAO    | 7         |
|                                | Pupil peer-assessment             | PPA    | 5         |
|                                | Group work: revision              | GWRev  | 1         |
| General                        | Including parents                 | IncP   | 1         |
|                                | Posters                           | Post   | 1         |
|                                | Presentations                     | Pres   | 1         |
| Total                          |                                   |        | 102       |

phrases whose meanings differed from teacher to teacher (even within the same school).

Practically every plan contained a reference to focusing on or improving the teacher's own questioning techniques although not all of these gave details of the particular way in which they were going to do this (for example using more open questions, allowing students more time to think of answers or starting the lesson with a focal question). Others were less precise (for example using more sustained questioning of individuals, or improving questioning techniques in general). Some teachers mentioned planning and recording their questions. Many teachers also mentioned involving students more in setting questions (for homework, or for each other in class). Some teachers also saw existing national tests as a source of good questions.

Using comment-only grading was specifically mentioned by nearly half the teachers, although many foresaw problems with this, given school policies on grading. Four teachers planned to bring forward end-of-topic tests thus providing time for remediation.

Sharing the objectives of lessons or topics was mentioned by most of the teachers, through a variety of techniques (using a question that the students should be able to answer at the end of the lesson, stating the objectives clearly at the start of the lesson, getting the students to round up the lesson with what they had learned). About half the plans included references to helping the students understand the grading criteria used for investigative or exploratory work, generally using exemplars from students from previous years. Exemplar material was mentioned in other contexts such as having work on display and asking students to correct work using a set of criteria provided by the teacher.

Almost all the teachers mentioned some form of self-assessment in their plans, ranging from using red, amber or green 'traffic lights' [stop lights] to indicate the student's perception of the extent to which a topic or lesson had been understood, to strategies that encouraged self-assessment via targets which placed responsibility on students (eg one of these twenty answers is wrong: find it and fix it!). Traffic lights (or some equivalent) were seen in about half of the plans and in practically all cases their use was combined with strategies to follow up the cases where the students signaled incomplete understanding.

Several teachers mentioned their conviction that group work provided important reinforcement for students, as well as providing the teacher with insights they into their students' understanding of the work.

The choices of activities by the different teachers also showed no particular pattern, as the multidimensional scaling (Schiffman, Reynolds, & Young, 1981) of these data in figure 2 shows.

The other component of the intervention, the visits to the schools, provided an opportunity for project staff to discuss with the teachers what they were doing, and how this related to their efforts to put their action plans into practice. The interactions were not directive, but more like a holding up of a mirror to the teachers. Since project staff were frequently seen as 'experts' in either mathematics or science education, there was a tendency sometimes for teachers to invest questions from a member of the project team with a particular significance, and for this reason, these discussions were often more effective when science teachers were observed by mathematics specialists, and vice-versa.

We aimed for each teacher to be observed six times over the school year from September 1999 to July 2000, although releasing teachers to discuss their lessons either before or afterwards was occasionally a problem (and schools that had guaranteed teacher release for this purpose at the beginning of the project were sometimes unable to provide for this).

### **Research Design**

Given the nature of the intervention, which was designed to build on the professionalism of teachers (rather than imposing a model of 'good formative assessment'

Figure 2. Multidimensional scaling of teacher action plan data.

on them), we felt that to utilize a traditional research design on the teachers would have been inconsistent. Furthermore, it would have been impractical. Since each teacher was free to choose which class would be the focus for this work, there was no possibility of standardizing either the 'input' or 'output' variables. For this reason, the collection of empirical quantitative data on the size of effects was based on an approach, which we have termed 'local design'. Drawing more on interpretivist than positivist paradigms, we sought to make use of whatever assessment instruments would have been administered by the school in the normal course of events. In many cases, these were state-mandated assessments such as the national tests for 14-year-olds or grades achieved in the national school leaving examinations (the General Certificate of Secondary Education or GCSE). In other cases we made use of scores from school assessments (particularly in science, where 'modular' approaches meant that scores on end-of-module tests were available). For each teacher we therefore had a focal variable (i.e. dependent variable or 'output') and in all but a few cases, we also had reference variables (i.e. independent variables or 'inputs'). In order to be able to interpret the outcomes we discussed the local circumstances in their school with each teacher and set up the best possible control group consistent with not disrupting the work of the school. In some cases this was a parallel class taught by the same teacher in previous years (and in one case in the same year). In other cases, we used a parallel class taught by a different teacher and, failing that, a non-parallel class taught by the

same or different teacher. We also made use of national norms where these were available. In almost all cases, we were able to condition the focal variable on one or more reference variables, although in some cases the reference variables were measures of aptitude (e.g., NFER's Cognitive Abilities Test) while in others they were measures of achievement (e.g., end-of-year 8 tests).

In order to be able to compare the results, raw differences between experimental and control groups were standardized by dividing by the pooled standard deviation of the experimental and control scores.

## Results

Table 4 provides the results achieved by the 19 teachers for whom controls were available and the standardized effect sizes are summarized in stem-and-leaf form in figure 3. As can be seen, the majority of effect sizes are around 0.2 to 0.3, with a median value of 0.27 and a mean of 0.34. Since the effect sizes were not normally distributed, the jack-knife procedure recommended by Mosteller and Tukey (1977) was used which provides an estimate of the true mean as 0.32 and a 95% confidence interval of the true effect size as (0.16, 0.48).

In order to examine the relationship between a teacher's practice and the effect sizes, we classified teachers into one of four groups, according to their use of formative assessment strategies in their classrooms:

|                             |  |
|-----------------------------|--|
| <i>Experts</i>              | Formative assessment strategies embedded in and integrated with practice.  |
| <i>Competent performers</i> | Teachers who were successful with one or two key strategies, but having routinized these, were looking for other ways to augment their practice. |
| <i>Advanced beginners</i>   | Teachers who were successful with one or two key strategies, and had restricted themselves to these.   |
| <i>Novices</i>              | Teachers who had attempted strategies, but had not embedded any strategies into their practice.  |

These characterizations had emerged from our observations of each teacher's practice, and were based on their use of key strategies during the main period of the project. Independent classification of the 24 teachers by the two main researchers produced identical classification for all but two teachers, and these were resolved after discussion. The effect sizes by teacher type are shown in table 5. Although there is no obvious trend in terms of average effect size, as one moves from less to more expert teachers, the interquartile range of effect sizes reduces, indicating further support for the attribution of the effects to the quality of classroom assessment.

A comparison of the effects by different forms of control in the form of side-by-side stem-and-leaf diagrams (figure 4) shows that no significant difference in effect sizes for the different form of controls is apparent.

Figure 3. Overall standardised effect sizes.

There was no difference in the mean effect size for groups of different ages, although it is worth pointing out that the year 11 (grade 10) focal groups all had positive effect sizes. There was no systematic variation in effect size by track. Analysis by subject shows that all the negative effect sizes were found for the mathematics groups, although the median effect sizes for the mathematics and science groups were almost identical.

### Discussion

By its very nature, the quantitative evidence provided here is difficult to interpret. The controls are not equally robust. In some cases, we have comparisons with the same teacher teaching a parallel class in previous years, which, in terms of the main question (ie has the intervention had an effect?) is probably the best form of control. In other cases, we have comparisons only with a different teacher teaching a parallel class, so it could be that in some cases a positive effect indicates only that the teacher participating in the project is a better teacher than the control. In other cases, the control is another class (and sometimes a parallel class) taught by the same teacher, and while there are examples of positive effect sizes here (in the case of Robert, for example) it is also reasonable to assume that the observed size of such effects will be attenuated by what we have termed 'uncontrolled dissemination'. In some cases, the only controls available were the classes of different teachers teaching non-parallel classes, and given the prevalence of ability-grouping in mathematics and science, and its effect on achieve-

Table 5. Effect sizes Classified by Teachers' Use of Formative Assessment Strategies

| Group           | Count | Median | Interquartile Range |

Figure 4. Standardised effect sizes by control type.

ment (see Wiliam & Bartholomew, 2001) disentangling the effect of our interventions from contextual factors is quite impossible. However, given the fact that the outcome variables were either national tests and examinations, or assessments put in place by the school, rather than devised by the teacher, we have some confidence that these measures have some validity in terms of what the teachers were trying to achieve, and, more importantly, that teachers do not have to choose between teaching well and getting good results.

However, the improvements in the achievements of students are not the only (nor perhaps the most important) outcome of this project. While a small number of our teachers did view involvement in the project as a short-term commitment, after which they would return to teaching 'normally', for the vast majority of our teachers, involvement in the project has not just spread to all their classes, but has fundamentally altered their views of themselves as professionals (Black, Harrison, Lee, Marshall and Wiliam, 2002). They not only enjoy their teaching more, but also have become ambassadors spreading the message to other teachers.

### Conclusion

In this paper, I have argued that by trying to emulate the 'hard sciences' educational research has taken a wrong turn. Expertise in teaching does not consist of more and more complex explicit schemes for determining action (as is the case for example, in quantum physics), but is, rather, beyond rationality. Expertise is the ability to 'feel' what is the right thing to do, not after long deliberation, but immediately, and intuitively and this intuition is not instinctive, but is the result of the sedimentation of vast numbers of examples of experience. The role of the researcher in supporting the development of such expertise is not to attempt to distil expertise down to its essence, but to encourage its development in others. We cannot 'bottle' this for widespread distribution, but we can support communities of teachers by highlighting profitable directions in which they might develop their practice. At the end of the project, we are left with a final irony. In allowing the teachers to choose what they developed in their practice (so that each teacher was, in effect, engaged in a unique experiment) we have given up the ability to say what worked. We know that the process in which the teachers were engaged was productive, but we cannot say which elements worked, and which did not. In allowing the teachers to create their knowledge, we have given up the ability, as researchers, to make our own particular knowledge claims. So be it.

# **Working Groups**

## WORKING GROUP ON GENDER AND MATHEMATICS: GATHERING REFLECTIVE VOICES

Diana B. Erchick  
The Ohio State University  
Erchick.1@osu.edu

Linda Condron  
The Ohio State University  
Linda.Condon @osu.edu

This paper reviews the history of the work of the PME-NA Gender and Mathematics Working Group, and the progress made toward the intended end product of the Working Group. The first section, Introduction and Review, outlines the history and work to date of the group. The second section, PME-NA XXIV Session Goals, delineates the plans of the group for the PME-NA IV sessions. The third section, Review of Contributed Voices, includes abstracts of the 13 papers submitted for the monograph project and being reviewed and discussed in this year's conference sessions. These papers are organized into four categories: *Reflecting on Voices in the Literature* includes three literature reviews; *Voices of Inquiry and Adolescent Girl* includes three papers reporting on adolescent girls' experiences with mathematics; *Voices from Post Secondary Classrooms* includes three papers reporting on work in post secondary mathematics and mathematics education classrooms; and *Voices (Re)Questioning* where four scholars raise questions about the work we do and future directions for inquiry around gender and mathematics.

### Introduction and Review

In all prior PME-NA Gender and Mathematics Working Group sessions from 1998 through 2001, we took the role of the "working group" to heart. We planned for the inclusion of *all* of participants in terms of being informed of the work to date and in participating in the work at hand. We plan and conduct the 2002 sessions similarly.

In 1998, at PME-NA XX in Raleigh, North Carolina, sessions centered around "Gender and Mathematics: Integrating Research Strands." We explored why we do the work we do and what we know from this work; what the compelling topics for future study are; and how we might further this work. Participants presented short papers and discussed connected issues. Organizer analyses of discussions revealed two main strands in the discussions: the "sex-gender system" and the "doing of mathematics." Participants created a web (see Erchick, Condron, & Appelbaum, 2000 for a visual representation of the web) to represent on-going work in gender and mathematics that illuminated for us the multidimensionalities of our scholarship. We concluded that the web represented research strands in gender and mathematics as well as new ways in which the group was thinking about the research strands.

In Cuernavaca, Morelos, Mexico in 1999, our PME-NA XXI Gender and Mathematics Working Group sessions were devoted to discussion, with the organizers responsible for synthesizing and analyzing each day's work. The first session was

framed by the summary of work at and since PME-NA XX and by work contributed by Dawn Leigh Anderson, Peter Appelbaum, Susanne K. Damarin, and Diana B. Erchick. In the second session, goals were set by the group: keep our work visible in the mathematics education community and work toward integrating our research findings into mathematics education and mathematics teacher education. Toward that end, we generated suggestions for how we might accomplish our goals: developing a monograph of our work; conducting research exploring practice; and, as suggested by Fennema and Hart (1994), pursuing research that is feminist and qualitative in nature. Participants developed an action plan and an organization for a call for papers for our monograph. Categories for the monograph included, but were not limited to the development of epistemological voice; the integration of gender research into the mathematics classroom, K-16; the integration of gender research into the mathematics education classroom; the role of the content in addressing gender issues in mathematics education research; mathematical success in fast-track and other programs for girls in mathematics; and mathematical success for women in mathematics and math-using fields.

At the 2000 PME-NA XXII Gender and Mathematics Working Group in Tucson, Arizona, we discussed in depth the ongoing work of all of the participants present at the sessions. This allowed us to understand some of the research that was already in progress by these working group members and to place that work within the context of the emerging themes of our intended monograph. We also developed a working thematic structure for the monograph where the concept of "Reflective Voices" guided the structure. We organized work around multiple perspectives that include researcher, historical, teacher, student and critical perspectives and these perspectives include feminist, methodological, self-reflective and empirical standpoints. We 1) generated ideas for the distribution of a call for papers; 2) defined group member participation in the creation of the monograph; and 3) planned continued connection in professional meetings over the upcoming year.

At the 2001 PME-NA XXIII Gender and Mathematics Working Group sessions at Snowbird, Utah, we shared draft papers intended for the monograph and welcomed a number of new participants into our group. We discussed the emerging work in the sessions and many of us had the opportunity to continue those discussions beyond the confines of our sessions. We planned guidelines and timelines for progress toward the monograph and have been able to meet the goals set in that planning since we left the conference in Snowbird. We now have 13 scholars with papers in preparation or completed and submitted to our monograph editors.

#### **PME-NA XXIV Session Goals**

For this, the 2002 PME-NA XXIV Gender and Mathematics Working Group in Athens, Georgia, we are organized into two sessions. In these sessions, we anticipate that, as has been true in the years of the Gender and Mathematics Working Group at

PME-NA, new members will join our ranks; some with the intention of submitting work to the monograph; others seeking the opportunity for scholarly discussion. We find these new members, their input, critique, questioning and insights, vital to the growth and development of our efforts in the group.

### **Session One**

During the first session a review of the progress of the PME-NA Gender and Mathematics Working Groups is in order. The focus of that review is the working outline of our developing monograph, *Research, Reflections, and Revelations on Gender and Mathematics: Multiple Perspectives & Standpoints* (Erchick & Condrón, 2001). We expect to critique the outline, review our submitted work for the project and determine how it reflects the essence of the monograph. We also plan to begin to review the submitted manuscripts. Working subgroups developed in this session will read, discuss and begin to provide feedback on and delineate needs of submitted papers.

### **Session Two**

Session two participants will attend with a familiarity and working knowledge of the monograph outline and contributed work. Subgroups will devote the second session to peer review and feedback on the structure, analysis, conclusions, and implications of the submitted papers. It is the goal of the group that all submitted papers have this internal review, feedback and support before final revisions, editorial reviews, and full manuscript submission.

### **Review of Contributed Voices**

When Suzanne Damarin and Diana Erchick started this project in 1998, an early result of the working group sessions was a graphic that revealed two conceptions determined by the scholars working within the group. One determination of the group was that the structure of our examination of the scholarly work of gender and mathematics was nonlinear and very complex. The other determination of the group was that there were absences in the field of study, and it would be part of our mission as members of the working group to pursue scholarly inquiry in directions that would begin to contribute to the field in the areas of those absences.

As we collect, review and organize the work our members have been conducting over the past few years, we do so with an "attunement" to the voices of the teachers, students and scholars participating in the work. As Erchick & Kos (in press) explain, "attunement implies a deliberate focus on particular concepts and the voiced representations of them. It is a special way of listening, a special way of hearing. It requires knowledge and understanding of the concepts heard as well as an effort to hear." Our attunement reveals both our committed effort to focus on participant voices in our work and the scholarly understanding we bring to that hearing. Following are examples of the work we now bring to this project. This project is not intended to be

a comprehensive satisfaction of the need to address the absences we have identified in the field of gender and mathematics; it is, however, intended to be a beginning.

### **Reflecting on Voices in the Literature**

In her contribution, *Research and Reflections on Women Leaving Post-Secondary Mathematics*, Abbe H. Herzig writes from the Graduate School of Education at Rutgers University. In her work she writes how women and members of some racial and ethnic groups are underrepresented at higher levels of education in science, mathematics, and engineering (SME). That is, at each educational stage, disproportionately fewer members of these groups persist in the study of SME disciplines. This is a concern both because of our need to ensure equitable and fair opportunities for all individuals, and because of the loss of the contributions that these students might otherwise make. Herzig explains how research effort has been invested in examining the loss of these students—particularly women—from particular stages of the SME educational “pipeline,” but few studies have focused particularly on mathematics. In her review, she draws out the parts of that research that are relevant to mathematics in particular, and reviews the research about females leaving mathematics. This review synthesizes research from various educational stages to present a longitudinal picture of women leaving mathematics, beginning in high school and throughout college and graduate school. Herzig includes her own reflections as a woman who left mathematics, and kept coming back, several times.

Linda Condon, from The Ohio State University, contributes a review of literature “stories” about women and the technical realm. There are stories throughout history that demonstrate women have always been active with/in science, mathematics, and technology. For example, Hypatia of Alexandria is famous for her work in algebra; Ada Lovelace wrote the first computer programs; and Grace Hopper was instrumental in the creation of modern computers and programming languages (Alic, 1986; Rositer, 1982; Stanley, 1983). There are also stories of the consistent absence of women from the technical realm. Less than a hundred fifty years ago, many people believed that women’s reproductive organs would be damaged if they studied mathematics and science (Solomon, 1985). Women were excluded from such study by official policies barring their access to formal education in many high schools, colleges, and engineering schools (Hacker, 1983). A story encountered by women in technical professions in our own times is that of marginalization. In the 1970s, women entered technical professions in record numbers. However, statistics indicate these well-educated women, working in the technical realm of today experience lower status and pay than their male counterparts (NSF, 1996). A compelling story can be gleaned from the writings of women like Evelyn Fox Keller (1985) who showed how science and the scientific method was conceptualized in 17th century Europe. Examining the metaphors used for science and technology, Keller reveals a story of science defined as male, a story within which women have no place from which to engage with/in the technical realm

without calling into question their very identities as women (Harding, 1986; Keller, 1985).

Another story about the relationship of women to mathematics and technology is one of how mathematics came to be a school subject, to be important in engineering education, and to be used as a “critical filter” that excludes women and certain other groups from technical educational opportunities (Cohen, 1982; Hacker, 1983; Sells, 1992). Condron interprets this vast and complex literature as numerous competing stories, sometimes overlapping, sometimes contradicting one another (Condron, 1997; Haraway, 1991; Lather, 1991).

Dawn Leigh Anderson, from California State University at Fullerton, contributes a theoretical framework that draws upon the literature on feminist standpoint theory. In *A Theoretical Framework for Inquiry: Feminist Standpoint Theory and Its Application to Mathematics Education*, Anderson discusses a feminist epistemological framework by beginning with the point that there is no one feminist epistemology. She admits to the many and diverse feminist epistemological frameworks and that nowhere will we find one true feminism or feminist epistemology. The feminist theoretical framework that Anderson relies upon in her work is feminist standpoint theory, one that most aptly describes the lens through which she approaches her work. She first provides an overview of feminist standpoint theory in order to familiarize readers with its main tenets; then she discusses the application of feminist standpoint theory to mathematics education.

Anderson cites Nancy Hartsock’s (1983) introduction of a “feminist standpoint” and traces the origins of standpoint theory in feminism back to Marxist thought, where the idea that the proletariat maintains a standpoint that is unique to the working class. Her points are made with a rich literature of feminist scholarship as she explains the tenets of feminist standpoint theory through discussion of women as constructors of knowledge; privileged epistemic viewpoint; agency; objectivity; and multiplicity. As she moves her discussion into mathematics education, Anderson includes topics like females as the focus of inquiry, mathematics as a gendered process, diversity, learning as a reciprocal activity, voice, agency, and authorship. She includes a discussion of epistemological perspective of mathematics within feminist standpoint theory and addresses the issue of “the risk of essentialism.” She draws on the work of scholars such as Burton (1995; 1999), Confrey (1994; 1995a; 1995b; 1999), Damarin (1990; 1995), Fuss (1989), and Rogers and Kaiser (1995). Anderson is committed to the idea that there is no single feminist perspective of doing, knowing, and learning mathematics. She strives to understand the diverse and multiple experiences of girls in feminist mathematics classrooms. She explores patterns and examines how those patterns affirm girls’ experiences in a feminist mathematics class.

### **Voices of Inquiry and Adolescent Girls**

Jae Hoon Lim, from the University of Georgia, contributes her paper, *Sociocultural Contexts of Learning School Mathematics: Impact of Social/Cultural Capital*

on Girls' Motivation and Identity to this project. The theoretical framework of this study is derived from the recent accomplishments of social constructivism and critical ethnography in education. Lim identifies critical perspectives that argue the case that education helps to maintain the status quo. Practices and structures marginalize or deny groups of people from society's influential positions. These groups of people include women, minorities, and members of low socioeconomic classes. She cites scholars such as Apple (1988), Calhoun (1993), Harter, Waters, and Whitesell (1997), Oakes (1990; 1992) in her arguments.

The work she reports upon here is a cross case study. Lim explores two young adolescent girls' experiences with school mathematics. The impact of the sociocultural context upon their motivation and mathematical identity is a focus. Lim conducted repeated in-depth interviews and ethnographic observations of the girls' mathematics classroom, and portrays two contrasting pictures of young adolescent girls who come from different ethnic, economic, and cultural backgrounds. The interview data revealed three themes. One is that the girls' experienced an anxiety that was grounded in the school mathematics culture. A second theme is that social and cultural capital contributed to the girls' motivation and identity construction. The third emergent theme for the girls is the "problematic dislocation between their social world and their experience with school mathematics."

Lim reports that "[t]he overall data analysis reveals the profound impact of social/cultural capital upon the girls' experiences with school mathematics well as their construction of identities in the discipline" and "illuminates the ways in which various sociocultural factors and forces dynamically impact aspects of their identities and motivation for learning school mathematics."

Ann C. Howe and Sarah B. Berenson report from the Center for Research in Mathematics and Science Education at North Carolina State University. In their paper, *Talented Girls Talking About Their Attitudes, Experiences and Expectations in Mathematics*, they describe work that focuses on twelve middle class, mathematically talented girls' as they talk about their attitudes, experiences and expectations related to mathematics. They also ask whether teachers see the girls as the girls see themselves. The paper is based on interviews of girls who participated in *Girls on Track*, a summer and follow-up program for ethnically diverse middle school girls who are enrolled in upper level math courses, and the results of a survey of teachers and counselors in the project. Howe and Berenson interviewed the girls and coded their data for interest, motivation, confidence, parental (and others') support, readiness, general self esteem, usefulness of mathematics and career plans. They also asked the girls to respond to a written questionnaire; teachers and counselors responded to two similar forms of the instrument, one to assess attitudes toward girls and mathematics, the other to assess attitudes towards boys and mathematics.

The results of the interviews confirm what is expected for girls who are on the upper math track. In their own words they tell us that they like math, their parents

expect them to do well and they are willing to put forth the necessary effort to maintain good grades. Most of them are self confident, optimistic, have many interests, are involved in a variety of activities, have thought about their futures and expect to have professional careers. When Howe and Berenson analyzed the teachers' and counselors' responses to the survey instrument they found no significant difference in attitudes toward boys and girls in math. However, they found that the girls scored themselves somewhat higher in every category than teachers and counselors scored girls. That is, the girls are more interested, confident, motivated, and aware of priorities, stereotypes and gender than their teachers believe girls to be. The paper explores and reflects on these findings.

Diana B. Erchick contributes a report from an evaluation of a summer mathematics camp project implemented through The Ohio State University. Her paper, *Mathersize Camp for Middle Grades Girls: Reflections on Content and Process*, describes the perceptions of girls and teachers who participate in the camp, and the parents of the girls who participate. The camp is a weeklong summer project where lessons integrate mathematics with science, art and literacy. The Mathersize program intends to support the mathematical development of its participants through implementation of research-based curriculum and instruction and informed pedagogy.

Erchick explains how, to support understanding and connection in mathematics, the Mathersize camp focuses on providing meaningful mathematics experiences based on three criteria: 1) a curriculum and pedagogy grounded in recommendations of the learned societies and their research-based recommendations both for pedagogy and equity (NCTM 2000; Erchick, 2002a); 2) support for a process-based epistemology (Erchick, 2002b) in understanding the content of mathematics; and 3) development of community by girls during their school experiences with mathematics. Erchick conducted the evaluation from an interpretivist perspective (Denzin, 1989; Schwandt, 1994), a methodological focus that was particularly relevant in terms of generating findings grounded in students' interpretation of the experience of mathematics education – what role the content plays in their development; how meaningful the content is in their lives; how it does or does not contribute to the students' quality of life; how selected pedagogies and supports serve their needs; and how the girls interpret efforts to support their continued networking around mathematics.

All data collected for evaluation purposes was a part of the usual implementation and evaluation of the camp and consisted of application essays, daily writing samples, work products from the camp, feedback questionnaires from parents, and students and teachers participating in the camp. Erchick's analysis revealed the presence of a process-based epistemology and the ways in which the camp's pedagogical focus supported that epistemology. Analysis also revealed how the girls attending the camp perceived the social connections made in the camp to be important and meaningful. It is not inconsequential that the social connections centered on mathematics experiences.

### **Voices from Post Secondary Classrooms**

Dorothy Buerk, from Ithaca College, contributes work entitled "Listening to Women in College Mathematics Classes." In quotations from remarkably articulate women, she hears a metaphor of math as a stainless steel wall, offering no handhold, on which are written innumerable God-given rules of mathematics. She also hears "math is not a place for ideas in process" (Buerk & Szablewski, 1993, p.152); and "there seemed no room for interactions with the content, no possibility of connection with the ideas" (Buerk & Szablewski, 1993, p.151).

Many students believe that mathematics is made up only of rules, formulas, and proofs to be memorized; skills to be practiced; and methods to be followed precisely. They believe that mathematics is a discipline where certainty is secure; where all questions have answers, which are known to authority (mathematician, professor, TA, textbook); where memorization, hard work, and some mystical quality called the mathematical mind are required. Buerk hears mathematicians report that the way mathematics is taught in the traditional classroom, in textbooks, and in their professional writing is the public image of mathematics. However, the way mathematicians do mathematics—the private world of mathematics—is intuitive, contextual, and narrative, involving experiencing the problem, relating it to their personal lives, and examining and resolving ambiguities (Buerk, 1985). Buerk relates this gap between the conception of mathematics of many students and the conception of mathematics often held by mathematics educators to the theories of Perry (1970, 1981) and Belenky, Clinchy, Goldberger & Tarule (1986). In her research, she presented women a series of mathematical experiences to encourage growth in conceptions of mathematical knowledge through successive positions in Perry's scheme, and observed parallel progression toward personal responsibility for their own learning, with mathematics becoming more approachable for them (Buerk, 1981, 1982). In the absence of such classroom experience of mathematics, Buerk is compelled to return to the provocative question posed by Elizabeth Fennema, "Is it possible that females have recognized that mathematics, as currently taught and learned, restricts their lives rather than enriches them?" (Fennema, 1994).

Kathleen L. Bonn, from Michigan Technological University has contributed a paper entitled *What Factors Affect Women's Decisions to Pursue Graduate Degrees in Mathematics?* In this work Bonn discusses nine college seniors, all women majoring in mathematics at a mid-size Midwestern research university. She points out that currently 50% of the bachelor's degrees in mathematics are now going to women; but given that so many women now major in mathematics, it is unusual that not one of these nine women had plans to pursue a graduate degree in mathematics. They had come to dislike mathematics, yet planned to get a job teaching high school mathematics.

Bonn's objective in this study was to understand how senior female mathematics majors made decisions about continuing on in mathematics. She conducted in-depth

individual interviews and focus group interviews. Through the interviews Bonn asked participants questions regarding their educational histories in high school and college mathematics. She asked also questions about role models and questions about future plans. In additional interviews, seven participants with high grade point averages, and thus the background to enroll in graduate-level mathematics programs, were asked to focus directly on the questions, "What are the factors that directly or indirectly influenced *your* decision on whether or not to attend graduate school in mathematics?" and "What are the factors that could directly or indirectly influence *other female math majors'* decisions on whether or not to attend graduate school in mathematics?" Bonn found three major factors which affected these women's decisions: (lack of) confidence in one's ability to do graduate-level mathematics, (lack of) perceived usefulness of a graduate degree in mathematics, and (lack of) enjoyment in mathematics. Bonn makes two recommendations: encourage more women to attend graduate school in mathematics and support mathematics education majors so that they will reenter high school classrooms enthusiastic about mathematics and confident in their abilities to foster this love of mathematics in their own students.

Hea-Jin Lee, from The Ohio State University at Lima, contributed *The Evolution of Prospective Teachers' Perceptions of Teaching*. She reports on work with preservice elementary and middle school teachers. Lee analyzed interviews, journal entries and concept maps, to investigate changes in the total number of items on the maps; the number of item streams (superordinate concepts close to the central concept); hierarchical organization; increased similarity to one another; use of technical vocabulary and frequently used terms introduced in the program.

Lee's findings point to the importance of understanding preservice teachers' prior beliefs to inform supervision and university course design; the need to routinize classroom management knowledge before attending to subject-specific pedagogy; and the importance of the academic task as part of the teaching knowledge base. Many students listed terms such as lesson preparation, attention, enthusiastic teaching, and teaching aids. Other frequent item streams included humor, reinforcement, and classroom management. There was a general lack of technical vocabulary evidenced on the maps, as well as a lack of detail and hierarchical organization.

Lee cites Pajares (1993) with suggestions for several approaches to challenging beliefs; and the work of Feiman-Nemser and Buchmann (1989) to discuss the tension between challenge and support, assimilation and accommodation, tensions that must be tolerated and cultivated. Lee discusses preservice students' evolution; connections between teacher beliefs and how they choose to teach (Anning, 1988); and research on changing beliefs and teaching patterns to make them more constructivist and student oriented. This work becomes particularly significant when considering the demographics of preservice programs. With females dominating the profession, the issue could very well become the ways in which women in the profession perpetuate beliefs about mathematics and how they use those beliefs to shape instruction for student

learning. Indeed, how might these teachers teach the young in their care to learn to see mathematics? If the teachers approach mathematics as they do in Lee's study, women in elementary and middle grades education may model and teach their own beliefs and understanding, found in Lee's work to lack technicality, detail and hierarchical organization.

### **Voices (Re)Questioning**

In her work at the University of Wisconsin-Madison Ólöf Björg Steinpórsdóttir studies students' strategies in solving proportion problems and the influence of problem semantic type and number structure on the use of strategies. Steinpórsdóttir also examines gender differences in strategy use. For the work she discusses for this project, she interviewed twenty-seven females and twenty-six males - all eighth grade students in one school in Reykjavik, Iceland. The problems used in her study represented four semantic structures, four problems of each structure. Each problem represented a distinct number structure. Steinpórsdóttir finds that number structure influenced strategy use and success to a greater extent than semantic type.

In her paper, *Less sophisticated girls? Or less sophisticated analysis*, Steinpórsdóttir's analysis does not end with strategies and successes. With a cognitive lens in analysis, Steinpórsdóttir focuses on "sophistication" of strategy and strategy use. She finds no gender differences identified in the overall success rate at solving these problems. Girls were more successful than boys in associated sets and symbolic problems; and boys more successful than girls in part-part-whole problems. Girls and boys used different types of strategies for all semantic types except the symbolic. Data suggest the semantic type influences females' choice of strategy more than that of males.

Steinpórsdóttir problematizes her analysis and looks at how this traditional cognitive analysis portrays a deficit model of girls. It therefore sustains the common belief that girls don't do as well as boys in math. After analysis she critiques her own analysis, presentation of results, and the discourse used in her reporting. Her intention is to reconstruct the terms less and more sophisticated and less and more mature strategies, toward more gender-fair implications and a new discourse for discussing girls' and boys' achievement in mathematics.

Suzanne K. Damarin, from The Ohio State University, in her paper, *As the World Turns: Salient Issues on the Study of Gender and Mathematics*, discuss both a linear progressions model and a "world turning" metaphor to discuss models of research around gender and mathematics. The linear progressions model begins with a set of findings and uses that one set of findings to build upon another. It includes the idea of progress, of one day coming to a final solution. The world turning metaphor is a cyclic one that Damarin finds more suitable for the study of gender and mathematics. In this model, each new day/season/year researchers in the field of gender and mathematics find the same issues and experiences as they have always found. Instead of this indicating an endless circle, the model indicates constant (re)encounters with concepts

that are changing in the always new situations, always evolving contexts for returning issues of equity, power, agency, and voice.

Damarin starts her discussion with multiple critiques: of sex versus gender, essentialism in multiple venues, the denial of agency, and mathematics as a male domain. She then moves to a discussion of postmodernism as “both a condition and a philosophy, a mode of thought, a way of knowing.” From this perspective, she returns to the critiques in the earlier part of her paper. Damarin deconstructively reconsiders those critiques in one reprise after the other entitled Both Sex and Gender, Anti-Anti Essentialism, Subjected Positions, and Maleness as a Mathematical Domain. She closes with thoughts on the promise for the future with regard to Technology, Cyber Feminism, The Information Age, and Cultural Change.

Bob Klein, from The Ohio State University, in his paper, *Computer Calculus: Integrating Technology (with respect to sex)*, interrogates issues that lie at the intersection of technology, gender issues, and pedagogy. He asks the questions: How are pedagogies identified as being “female-friendly” or “feminist” enacted within a calculus reform classroom; How are feminist transformative desires approached by the enactment of these pedagogies? How are pedagogies contextualized? What implications arise from looking at ways in which pedagogies reflect (or not) the inclusive aims of feminist pedagogies and how accurate is the repeated use of “for all” as a label of inclusivity within educational discourse? Klein asks his questions of the site in terms of how the pedagogy was mediated by the use of technology. Klein collected data from a variety of sources surrounding a computer calculus course at a large Midwestern university in fall 2000. He identifies “Female-friendly” or “feminist” pedagogies as educational practices as having great potential to transform existing social relations thereby making our classrooms environments that embrace human diversity. Yet, taken uncritically or applied superficially, these techniques, when blindly applied “for all” can serve ends that are counterproductive to feminist transformative desires.

Peter Appelbaum, from Arcadia University, contributes “What Do We Learn From Critical Theory and Media Studies?” and asks us to construct questions about power, knowledge, and social change. He discusses the increasing sophistication of our comprehension of gender issues in mathematics and how that gets reduced to popular, common sense pronouncements on the need of female students for special help; and the need for funding for innovative programs that “solve the problem.” Appelbaum explains that the “increasing sophistication” comes from a consistent program in feminist epistemology and critique of mathematics as a disciplinary project and curricular encounter (e.g., Barton, 1998; Damarin, 1995). Strides made in reframing questions get translated in the mass culture as a threat to the commonsense notion that a neutrality and skill-based body of facts and procedures define mathematics. Any attempt to make mathematics meaningful, relevant or intellectually engaging for all becomes “a discursive interjection in the math wars debate between two constructed

poles: traditional and “fuzzy” math.” Special classes for girls sustain beliefs that the end result must be the “real,” or traditional curriculum and girls should be compared as a category to norms outside the category. “Even if the objectives of a special program for girls adhere to standards of ‘workplace readiness’ and basic skill levels, however, the program itself can never be a model for the standard curriculum, but is doomed to special ‘remedial’ or ‘epidemiologically preventive’ status.” Efforts to promote “girl power” and celebrate the accomplishments of girls and women in mathematics, serve to recreate glass ceilings for participation and performance while introducing new infrastructures and challenging the goals of traditional school programs.

Appelbaum points to an unbalanced view of the scenario on cultural change and social action, a view once posited by the anthropologist Marshall Sahlins (1985). People act to maintain social structure, but must change things to maintain that structure. Appelbaum makes the point that “what critical theory can help us with is the importance of power in the acting out of such action and social change. It is essential that we ask how knowledge is constructed as canonical or central to school practice, and why other knowledge is not.”

### Closing

In pursuing inquiry around the absences in the research on Gender and Mathematics, the PME-NA Gender and Mathematics Working Group participants have committed themselves to an interpretation of the field of gender and mathematics as complex and nonlinear. We have also chosen to investigate the absences we encounter with a respect for the reflective voices of the researchers, teachers, students, women and girls who contribute to the work. In the papers and processes of this project, we work consistently to respect the structure and voices that emerge.

### Acknowledgements

The authors thank all of the contributing scholars named in this paper, without whose collaborative efforts to abstract and represent their work here, this paper would not have been as rich.

In this workshop, we will continue to reflect on *a models and modeling perspective* to understand how students and teachers learn and reason about real life situations encountered in a mathematics and science classroom. We will discuss the idea of a model as a conceptual system that is expressed by using external representational media, and that is used to construct, describe, or explain the behaviors of other systems. We will consider the types of models that students and teachers develop (explicitly) to construct, describe, or explain mathematically significant systems that they encounter in their everyday experiences, as these models are elicited through the use of model-eliciting activities (Lesh, Hoover, Hole, Kelly, & Post, 2000). During the workshop we will continue to explore these aspects of learning, teaching, and research by continuing our work in smaller groups focusing in: Student Development, Teacher Development, Assessment, Curriculum Development, Problem Solving, and an emphasis on Research Design.

### **Highlights of a *Models and Modeling Perspective***

According to this perspective, models are conceptual systems (consisting of elements, relations, operations, and rules governing interactions) that are expressed using external notation systems, and that are used to construct, describe, or explain the behaviors of other systems. A mathematical model focuses on structural characteristics of the relevant systems (Lesh & Doerr, in press). These models reside inside the minds of the learners *and* are embodied in the equations, diagrams, computer programs, or other representational media. Because models are conceptual systems, they are partly internal and are similar to the conceptual systems that cognitive scientists refer to as cognitive structures. Nevertheless, the conceptual systems that are most powerful and useful seldom function in sophisticated ways unless they are expressed using spoken language, written symbols, concrete materials, diagrams or pictures, computer programs, experience-based metaphors, or other representational media.

Students have preconceived notions about many important mathematical constructs. However, it is impossible for anyone to know exactly what's inside a students' mind. But, when students are asked to develop a model (which is expressed in some kind of representational media), many inferences can be made about the nature of their mathematical knowledge and its development. These representational systems encourage students to externally present their ideas on paper or other media. Therefore, the external representations that these students create are a means for researchers and

teachers to view how students are thinking. In an analogous situation, when teachers are asked to develop a model about their students' ways of thinking, this model becomes a powerful window to view how teachers are thinking about this situation.

In order for students and teachers to externalize their understanding of complex situations, we have created different tools that elicit this type of thinking. Model-eliciting activities require students or teachers: (1) to develop a model that describes a real-life situation, (2) that encourages the solver to describe, revise, and refine their ideas; and (3) that encourages the use of representational media to explain (and document) their conceptual systems. These activities are similar to many real life situations in which mathematics is useful. Model-eliciting activities can be designed to lead to significant forms of learning because they involve mathematizing –by quantifying, dimensioning, coordinating, categorizing, algebraizing, and systematizing relevant objects, relationships, actions, patterns, and regularities.

For example, model-eliciting activities designed for students are intended for the solvers to reveal the way they are thinking about a given real-life situation that can be modeled through mathematics. These activities present real-life problem, to be solved by small groups of 3-5 students. The solution calls for a mathematical model to be used by an identified client, or a given person who needs to solve the problem. In order for the client to implement the model adequately, the students must clearly describe their thinking processes and justify their solution. Thus, they need to describe, explain, manipulate, or predict the behavior of the real world system to support their solution as the best option for the client. Like in real life, there is not a single solution, but there are optimal ways to solve the problem.

Model-eliciting activities are designed to engage students in developing math concepts. They set the students into a familiar context in which they are able to understand a need to develop powerful math ideas in order to solve a problem that is meaningful to them. That is, they are given a purpose to develop a mathematical model that best explains, predicts, or manipulates the type of real-life situation that is presented to them. Thus, students are forced into a cognitive situation where they can refine their mathematical ideas iteratively until they develop a construct that is useful and meaningful for them and for their client. Students' descriptions, explanations and constructions given to the client reveal how they are interpreting the mathematical situations they encounter by disclosing how these situations are quantified, organized, coordinated, and interpreted. In this way, model-eliciting activities allow students to document their own thinking and learning development.

A more complete description of *a models and modeling perspective*, written by many of the leading participants in this workshop, can be found in the book *Beyond Constructivist: A Models & Modeling Perspective on Mathematics Teaching, Learning, and Problems Solving* (Doerr & Lesh, in press). This book including chapters that focus on student development (Aliprantis & Carmona, in press; Dark, in press; John-

son & Lesh, in press; Kardos, in press; Lehrer & Schauble, in press; Lesh & Carmona, in press; Lesh, Zawojewski, & Carmona, in press; Oakes & Rud, in press;), teacher development (Doerr & Lesh, in press; Koellner Clark & Lesh, in press; McClain, in press; Schorr & Lesh, in press; van Reeuwijk & Wijers, in press), curriculum development (Carlson, Larsen, & Lesh, in press; Cramer, in press; Lamon, in press; Lesh, Cramer, Doerr, Post, & Zawojewski, in press; Shternberg & Yerushalmy, in press), and problem solving (English & Lesh, in press; Harel & Lesh, in press; Kehle & Lester, in press; Lesh, Lester, & Hjalmarson, in press; Lester & Kehle, in press; Middleton, Lesh, & Heger, in press; Zawojewski & Lesh, in press; Zawojewski, Lesh, & English, in press).

### Research Design from a *Models and Modeling Perspective*

A *models and modeling perspective* has proved to be a rich context for research and development. One of the main points of convergence from the conclusions achieved by each of the groups in the past workshops resided on the need for innovative designs for research and assessment that can help answer questions that involve the understanding of complex situations that are dynamic and iterative. Through the work that main participants of this workshop have been doing in each of the areas: Student Development, Teacher Development, Assessment, Curriculum Development, and Problem Solving, collaborative work has been done in innovative research design.

The *Handbook of Research Design in Mathematics and Science Education* (Kelly & Lesh, 2000) describes a variety of innovative research designs that have been developed by mathematics and science educators to investigate interactions among the developing knowledge and abilities of students, teachers, and others who influence activities in mathematics and science classrooms. This handbook has helped in setting the foundations to identify several characteristics that distinguish the type of research design needed to answer the types of questions we are most interested in, which at the same time, lead to the need of new research designs in mathematics and science education:

First, it is important to radically increase the relevance of research to practice—often by involving many levels and types of practitioners in the identification and formulation of problems to be addressed- or in the interpretation of results, or in other key roles in the research process. So, instead of having only one-way transmission of research into practice, research methodologies that are proving to be most useful in mathematics and science education often involve bi-directional interactions and iteratively evolving feedback loops among many levels and types of participants (students, teachers, researchers, curriculum designers, policy makers).

Second, in mathematics and science education, most of the things that need to be understood and explained are complex systems—not necessarily in the strict mathematical sense, but at least in the general sense that they are dynamic, interacting, self-regulating, and continually adapting. That is, they do not simply lie dormant until they

are stimulated; rather, they initiate action, and, when they are acted on, they act back. In particular when they are observed and when information is generated about them, changes often are induced that make researchers (and assessments) integral parts of the systems being investigated. Furthermore, among the most important systems that mathematics and science educators need to investigate: (a) many do not occur naturally (as givens in nature) but instead are products of human construction, (b) many cannot be isolated because their entire nature tends to change if they are separated from complex holistic systems in which they are embedded, (c) many are not observable directly but are knowable only by their effects on other agents or events, and (d) most include a variety of interacting communities of agents whose interactions lead to:

- Feedback loops that produce second-order which may outweigh or change the influence of first-order effects,
- Emergent characteristics of the system-as-a-whole that cannot be derived from characteristics of the agents within these systems.
- Behaviors that are often inherently unpredictable.

Third, the mathematical models that are needed to describe and explain the preceding systems are not restricted to linear equations or other kinds of simple input-output rules that presuppose the existence of independent variables that can be isolated, factored out, or controlled (Lesh & Lamon, 1992). For example, because of recent advances in fields such as those focusing on *geographic information systems*, there has been an explosion of new software and technologies that are capable of using graphic, dynamic, and interactive multimedia displays to generate simple (but not simple minded) descriptions of complex systems ranging from weather systems, to traffic patterns, to biological systems, to dynamic and rapidly evolving economic systems. Consequently, it is no longer necessary for educational decision-makers to rely on reports that involve nothing more than simple-minded unidimensional reductions of the complex systems that characterize the thinking of students or teachers—or relevant communities.

Fourth, research is about knowledge development; and, not all knowledge is reducible to a list of tested hypotheses and answered questions. In particular, in mathematics and science education, the products that emerging new research designs are intended to emphasize often focus on the development of models (or other types of conceptual tools) for construction, description, or explanation of complex systems. When producing these latter types of products, distinctions are being made between: (a) model development studies and model testing studies, (b) hypothesis generating studies and hypothesis testing studies, and (c) studies aimed at identifying productive questions versus those aimed at answering questions that practitioners already consider to be priorities.

Based on the term and the characteristics described by Brown (1992) and Collins (1992), we will call such research design a “design experiment”. This type of research

design can be characterized through four general principles that apply to Design Experiments focusing on the development of constructs and conceptual systems used by students, teachers, or researchers.

We will use the term “participant”, to refer, generically, to students, teachers, curriculum developers, program developers, software developers, and other types of researchers, developers, or practitioners. This terminology is appropriate because, to investigate the nature of the developing constructs and conceptual systems used by any of these participants, the following principles should be expected to apply.

1. **The Externalization Principle.** Situations should be identified in which the relevant ways of thinking that are desired to investigate (and/or develop) are expressed in forms that are visible to both researchers and to relevant participants. Design activities naturally tend to lead to *thought-revealing artifacts*, like the model-eliciting activities (Lesh, Hoover, Hole, Kelly, & Post, 2000) described in the previous section. That is, the underlying design often is apparent in things that are designed; the underlying constructs often are apparent in complex artifacts that are constructed; and, the underlying models often are apparent in conceptual tools that embody them. In other words, in the process of designing complex artifacts and conceptual tools, participants often externalize their current ways of thinking in forms that reveal the constructs and conceptual systems that are employed. In this sense, then, the products may be referred to as *embodiments* of the relevant conceptual systems. Therefore, as the tools or artifacts are tested, revised, or refined, the underlying ways of thinking are also tested, revised, and refined. This tends to be true especially if the products are *conceptual technologies* in the sense that they include not only procedures for *doing* something, but also conceptual systems for *describing* and *explaining* the situations in which the artifacts or conceptual tools are intended to be useful. That is, the reason for developing these tools has to do with interpretation, description, explanation, or sense-making –as much as transformation, construction, or computation.
2. **The Self-Assessment Principle.** Design “specs” should be specified as criteria that can be used to test and revise trial artifacts and conceptual tools (as well as underlying ways of thinking) –while discerning products that are unacceptable, or that are less acceptable than others. The design “specs” should function as Dewey-style “ends-in-view”. That is, they should provide criteria so that formative feedback and consensus building can be used to refine thinking in ways that are progressively “better” based on judgments that can be made by participants themselves. In particular, ends-in-view should enable participants to make their own judgments about: (a) the need to go beyond their first primitive ways of thinking, and (b) the relative strengths and weaknesses of alternative ways of thinking that emerge during the design process. Productive ends-in-view also should require participants to develop constructs and conceptual systems

that are: (a) powerful (to meet the needs of the client in the specific situation at hand), (b) shareable (with other people), (c) re-usable (for other purposes), and (d) transportable (to other situations). In other words, both the tools and the underlying ways of thinking should be shareable and generalizable.

3. **The Multiple Design Cycle Principle (or the Knowledge Accumulation Principle).** Design processes should be used in such a way that participants clearly understand that a series of iterative design cycles are likely to be needed in order to produce results that are sufficiently powerful and useful. If design processes involve a series of iterative development>testing>revision cycles, and if intermediate results are expressed in forms that can be examined by outside observers as well as by the participants themselves, then auditable trails of documentation are generated automatically; and, this documentation should reveal important characteristics of developments that occur. In other words, the design processes should contribute to learning as well as to the documentation and assessment of learning.
4. **The Diversity and Triangulation Principle.** Design processes should promote interactions among participants who have diverse perspectives; and, they also should involve iterative consensus building –to ensure that the knowledge, tools, and artifacts will be shareable and reusable- and so that knowledge accumulates in ways that build iteratively on what was learned during past experiences and previous design cycles. In general, to develop complex artifacts and tools, it is productive for participants to work in small groups consisting of 3-5 individuals who have diverse understandings, abilities, experiences, and agendas. By working in such groups, communities of relevant constructs tend to emerge in which participants need to communicate their current ways of thinking in forms that are accessible to others. Once diverse ways of thinking emerge, selection processes should include not only feedback based on how the tools and artifacts work according to the ends-in-view that were specified –but also according to feedback based on peer review. In this way, consensus-building processes involve triangulation that is based on multiple perspectives and interpretations. So, the collective constructs that develop are designed to be shareable among members of the group; and, they are designed in ways so that knowledge accumulates.

These characteristics and principles are not at all unfamiliar to scientists who investigate complex systems in fields such as astronomy, biology, chemistry, or physics –or in design sciences such as architecture or artificial intelligence. Thus, a new project has been supported by the National Science Foundation, in which input from leading scientist from outside the fields of mathematics and science education who are experienced in the use of Design Experiment methodologies in their fields will be considered for appropriateness to answer some of the questions math and science educators are demanding from research. This new project will produce a sequel to the earlier

*Handbook of Research Design in Mathematics and Science Education* (Kelly & Lesh, 2000). Not only will the new book focus on design research methodologies, but it will also describe on new types of dynamic and iterative assessments that are especially useful in design research –where rapid multi-dimensional feedback is needed about the behaviors of complex, dynamic, interacting, and continually adapting systems.

### The Working Group at PME-NA XXIV

It is clear that mathematics and science educators have become increasingly aware of the fact that few of the most important problems they need to address are going to be resolved by only a single isolated study. Instead, understanding the types of complex systems we are interested in research nearly always require communities of researchers and practitioners, representing a variety of theoretical and practical perspectives, working together collaboratively over extended periods of time and across a variety of sites. The discussion during this workshop of the use of Design Experiments in Mathematics Education in each of the groups: Student Development, Teacher Development, Assessment, Curriculum Development, and Problem Solving, will provide an opportunity for all of the participants to begin or continue the development of these greatly needed communities of researchers and practitioners, to expand our focus of research and answer the types of questions we are being challenged by our field for this new century.

## **CURRICULUM MATERIAL AND ITS USES IN TEACHING AND LEARNING MATHEMATICS**

Yeping Li  
University of New Hampshire  
yeping@math.unh.edu

Karen Fuson  
Northwestern University  
fuson@northwestern.edu

As an outline of school educational activities, curriculum has been the focus of educational reforms in the past several decades (e.g., National Council of Teachers of Mathematics, 1980, 2000). In contrast, there are very limited research efforts given to examine the nature of mathematics curriculum and its roles in teaching and learning mathematics. Efforts to change curricula in the past have focused on revising and developing curriculum materials that were used in classrooms. Because curriculum materials have been a mainstay in mathematics classrooms in many education systems (McKnight, Crosswhite, Dossey, Kifer, Swafford, Travers et al., 1987; Schmidt, McKnight, & Raizen, 1997), it is often assumed that the quality of curriculum materials matters. However, previous reform efforts in changing curriculum materials have not been as successful as educators might expect (e.g., Kline, 1973; McKnight et al., 1987; Project 2061, 1999). Previous efforts and results in reforming curriculum, in fact, suggest the importance of developing research on mathematics curriculum. As a step toward a better understanding of the nature and effects of curriculum materials in teaching and learning mathematics, a discussion group was organized at PME-NA XXIII (Snowbird, UT; October 18-21, 2001). General issues on the quality and role of curriculum materials in mathematics education were discussed. This working group is proposed as a means to further discussions by drawing on continued investigation and collaboration on this topic. In particular, this working group will focus on the following two issues:

- (1) How can we examine the quality of curriculum material in terms of its content selection, presentation, and organization?
- (2) How can we examine the use of curriculum material in teaching and learning mathematics in classrooms?

### **Research Background**

Existing studies on the quality of curriculum materials have derived from two concerns: (1) possible contributions of curriculum materials to students' mathematics achievement, and (2) instructional features and functions embedded in curriculum materials. Examining possible contributions of curriculum materials to students' achievement was often taken in a direct and quantitative way in the 1950s and 1960s

(Walker & Schaffarzick, 1974) and was developed as measuring students' Opportunity-To-Learn (OTL) in more recent international studies (e.g., Robitaille & Garden, 1989; Westbury, 1992). Findings from previous studies suggest that curriculum materials are one of the key contributing factors to students' achievement. However, students' achievement cannot be solely explained by the differences in curriculum materials, and there are also much more in curriculum materials that need to be examined than simply measuring students' OTL. In particular, the instructional functions of curriculum materials are one aspect that has received research attention recently. Relevant studies have shown the feasibility and importance of examining instructional features embedded in curriculum materials in the United States (e.g., Project 2061, 1999) and in materials from different national education systems (Mayer, Sims, & Tajika, 1995; Schmidt et al., 1997). However, further efforts are needed to review, explore and discuss the types of features that are essential for comparing curriculum materials and determining their functions in facilitating the teaching and learning of mathematics.

Although curricular materials are a mainstay in mathematics classrooms in many education systems (Eisner, 1987; McKnight et al., 1987), the curriculum implemented in classrooms often combines with teachers' own thinking and planning (Doyle, 1993; Remillard, 1999). Examining the interaction between curriculum materials and teacher is a relatively new endeavor in curriculum studies. A few existing studies have examined teachers' use of textbooks in classrooms (e.g., Freeman & Porter, 1989; Stodolsky, 1989). For example, Stodolsky (1989) focused on comparing teachers' selections of content topics and instructional suggestions. She found that teachers consistently adhered to the content topics given in their textbooks, but departed from many accompanying instructional suggestions. Similarly, Freeman & Porter (1989) reported that teachers did not follow exactly what curriculum materials suggest they teach. Although few would disagree that there is a discrepancy between curriculum materials and what is implemented in classrooms, remarkable differences can be found from existing studies with regard to the extent curriculum materials affect teaching and learning mathematics in classrooms. Further research efforts are needed for a systematic and in-depth examination of the use of curriculum materials in teaching and learning mathematics in classrooms.

### **Plan for Involvement of Participants**

The working group will be organized as a two-part activity. During the first part, participants will introduce each other and then the two organizers will present brief (about 15 minutes) overviews and/or examples of relevant research. The purpose of this short presentation is to outline the historical development of curriculum studies and bring participants up to date about relevant studies. Samples of curriculum materials from different education systems will be brought to the working group and shared with all participants. After the presentation, the participants will be organized to join

the small-group discussions that will constitute the second part activity. The discussion in small groups will center on the two focal issues and will be facilitated with the examination and comparison of sample curriculum materials. After small-group discussions, all participants will come together to generate a collective summary and synthesis of the small-group discussions.

### Anticipated Follow-Up Activities

Based on activities to take place at Athens, a list of potential research questions will be selected and interested participants will be organized to develop further research activities on this topic after the meeting. The issues of curriculum materials in mathematics education can and should be examined with a variety of points of view. Collaborative work, based on participants' research interests, can be developed either cross-nationally or within the United States. Participants will be strongly encouraged to share their research and come together again in future PME-NA meetings.

### Connections to the Goals of PME-NA

This Working Group has emphasized research into the quality and uses of curriculum materials in mathematics education. The topic is developed from a long and broad range of studies on mathematics curriculum, instruction, and students' achievement, both within and across educational systems. Research on this topic draws on a rich background of psychological, pedagogical, and mathematical ideas, and it can open great opportunities for further study and collaboration. Thus, this Working Group connects to all three goals of PME-NA.

## **THE COMPLEXITY OF LEARNING TO REASON PROBABILISTICALLY**

Carolyn A. Maher  
Rutgers University  
cmaher3@comcast.net

Robert Speiser  
Brigham Young University  
speiser@mathed.byu.edu

Over the last several years, we have given serious attention to how students learn to reason probabilistically; that is, how learners construct mathematical models, and how these models interrelate with each other and with data. A special focus has been on how students build and work with information. Some of research along these lines has been reported and discussed at Singapore (ICOTS-5, June 21-26, 1998), at PME-NA 20 (North Carolina State University, Raleigh, North Carolina, October 31–November 3, 1998), at the third Robert B. Davis (RBD) Working Conference (Snowbird, Utah, May 22-26, 1999) at PME-NA 21 (Cuernavaca, October 23-26, 1999), PME-NA 22 (Tucson, October 7-10, 2000) and PME-NA 23 (Snowbird, October 18-21, 2001). Continuing discussion, investigation and collaboration draw on work at sites around the world.

### **Issues**

At PME-NA 20 (Raleigh, 1998), the Working Group began to formulate a joint agenda for research, discussion and investigation. At Cuernavaca, the Working Group at PME-NA 21 developed this informal research direction further, together with presentations of data and research results. Discussions at PME-NA 22 (Tucson) and at PME-NA 23 (Snowbird) continued and extended the past discussion, with particular emphasis on identifying important mathematical and psychological issues that our work suggests should be addressed by learners, researchers and teachers. Central issues which the group discussed include:

- Gaining more detailed understanding of how learners work with data, through analyses of learners' images, representations, models, arguments and generalizations. Attention to learners' successes as well as learners' difficulties, in the unifying context of research on the development of understanding.
- Attending to how models, reasoning and thinking function in communities of learners, teachers and researchers. Examination of the roles of given tasks, of classroom environments, of student-teacher interactions, and of how learners, in a range of settings, share ideas, reasoning, and information.
- Placing more fundamental emphasis upon the development of mathematical ideas through time, with learners of different cultures, ages, and social backgrounds;

and with different prior mathematical and scientific experience. Recognition of the importance of detailed analysis of learners' and researchers' changing views of underlying psychological, mathematical and scientific issues.

To help focus and develop this agenda, the Cuernavaca discussion took as starting points the interplay of combinatorial and probabilistic reasoning for constructing images and models in the course of task investigations. At Tucson, and at later meetings, the complex role of such key ideas as sample spaces and data distributions came into the foreground, as well as very stimulating questions and discussion centered on the role of simulations and experiments in the building, by learners, of important models and ideas.

### **Theoretical Framework**

Recent research emphasizes the complexity and subtlety of probabilistic reasoning, even in very basic situations. Models and representational strategies can easily extend distortions, even while they help support the growth of understanding. Indeed, the variety of representations which learners find useful, and the complex relationships among the models learners build and the data which they seek to explicate, provide rich opportunities for research investigations focused how learners, in social settings, construct, present, revisit and reconsider key ideas and ways of working. Indeed, given its complexity, the development of probabilistic thinking seems to *demand* reflective building over time. The tools available, the ways the tools are used, the ways in which ideas and information move among the learners, the teacher's questions, ideas and interventions, all contribute (or perhaps fail to contribute) in important ways. In our group's emerging view, both research and teaching need to take the need for long-term building, as well as the complexity even of very basic tasks, into account.

### **Background**

Related cross-cultural research on particular dice games, by researchers in several countries, using different methods of analysis across a range of settings and learner populations, was reported in joint sessions at the International Conference on the Teaching of Statistics (ICOTS-5, Singapore, June 21-26, 1998). The Singapore reports (Amit, 1998; Fainguelernt & Frant, 1998; Maher, 1998; Speiser & Walter, 1998; Vidakovic, Berenson & Brandsma, 1998) helped motivate the work at Raleigh. Further discussions at the third RBD Working Conference (Snowbird, Utah, June 1999) addressed important aspects of the Working Group's agenda in the context of the growth of understanding.

The present Working Group, first at Raleigh, then at Cuernavaca, and again at Tucson, built upon this shared research, enlisted new collaborators, and helped continue an evolving and quite lively conversation. An incomplete but perhaps representative list of active members of the Working Group would include Sylvia Alatorre, Fernando Hitt and Araceli Limon Segovia from Mexico; and Alice Alston, Sally

Berenson, George Bright, Hollylynne Stohl, Susan Friel, Regina Kiczek, Clifford Konold, Carolyn A. Maher, Bob Speiser, Pat Thompson, Draga Vidakovic, and Chuck Walter from the United States, and Claude Gaulin from Canada. Further colleagues, in several countries, are known to be engaged in work related to the Group's agenda and concerns.

### **Plan for Involvement of Participants**

At Raleigh, the Working Group considered data drawn from sixth-graders' work on two dice games (Maher, Speiser, Friel & Konold, 1998) which led to an extremely rich discussion. Based on this experience, a list evolved which at Tucson had come to include four tasks, which we invited participants at different sites to explore with diverse learner populations. Here are current versions of these tasks.

#### **A Game For Two Players**

Roll one die. If the die lands on 1, 2, 3 or 4, Player A gets one point (and Player B gets 0). If the die lands on 5 or 6, Player B gets one point (and Player A gets 0). Continue rolling the die. The first player to get 10 points is the winner. Is this game fair? Why or why not?

#### **Another Game For Two Players.**

Roll two dice. If the sum of the two is 2, 3, 4, 11 or 12, Player A gets one point (and Player B gets 0). If the sum is 5, 6, 7, 8 or 9, Player B gets one point (and Player A gets 0). Continue rolling the dice. The first player to get 10 points is the winner. Is this game fair? Why or why not?

#### **The World Series Problem**

In a "world series" two teams play each other in at least four and at most seven games. The first team to win four games is the winner of the "world series." Assuming that both teams are equally matched, what is the probability that a "world series" will be won: (a) in four games? (b) in five games? (c) in six games? (d) in seven games?

#### **The Problem of Points**

Pascal and Fermat, in correspondence, discuss a simple game. They toss a coin. If the coin comes up heads, Fermat receives a point. If tails, Pascal receives a point. The first player to receive four points wins the game. Each player stakes fifty francs, so that the winner stands to gain one hundred francs, and then they play. Suppose, however, that the players need to terminate the game before a winner is determined. Further, suppose this happens at a moment when Fermat is ahead, two points to one. In correspondence, Pascal and Fermat discuss the question: How should the 100 francs be divided?

The first two tasks, and extensions, for example with tetrahedral dice, were developed for sixth-graders in the Rutgers-Kenilworth longitudinal study by Carolyn A.

Maher and her collaborators. Related work includes (Kiczek & Maher, 1998; Maher, Davis, & Alston, 1991; Maher & Martino, 1996; Maher & Martino, 1997; Maher & Speiser, 1997; Martino, 1992; Martino & Maher, 1999; Muter, 1999; Muter & Maher, 1998). The last two tasks were developed initially for eleventh-graders in the Rutgers-Kenilworth study.

Research on several of these tasks has already taken place at several sites around the world. Work in Brazil (Fainguelernt & Frant, 1998), in Israel (Amit, 1998), and in at least four places in the United States (Berenson, 1999), (Kiczek & Maher, 1998), (Maher, 1998), (Speiser & Walter, 1998), (Vidakovic, Berenson & Brandsma, 1998) has already been reported. Closely related findings, including (Alatorre, 1999) and (Berenson, 1999), were discussed in detail by the Working Group at Cuernavaca.

At the Tucson session of the Working Group, still more recent research was presented. In particular, the group discussed an extended videotaped student discussion of the World Series Problem, from the Kenilworth long-term study, directed by Carolyn A. Maher. At the Snowbird meeting, the group's continuing discussions were further broadened and extended. Points of special emphasis included (1) the roles played by experiments and simulations in the building of ideas by learners, (2) the multiple ways in which learners present and reason about data, and (3) the complex use, in actual practice, of software and related tools. Much discussion concentrated on the following new task, introduced by Maher:

### **The Boy-Girl Problem**

There are two children in the house. You knock on the door, and a girl answers. What is the probability that the other child is a girl?

An extended written analysis of this problem by one student in the Kenilworth study was presented at Snowbird, after a very lively interchange among the members of the working group. At the Athens meeting, we look forward to further conversations based on task investigations, including recent work by Amit (in Israel) on children's thinking about the dice game tasks described above.

### **Anticipated Follow-Up Activities**

Collaborative work, based on case studies drawing on a focused set of tasks, and upon related research from a variety of points of view, at different sites in several countries, has already helped to focus and extend discussion and collaboration. Based on our continuing experience, further work with learners, in a range of settings, as well as further sharing and collaboration, are expected. In this spirit, we cordially invite new participants to join a growing and productive enterprise.

## GEOMETRY AND TECHNOLOGY WORKING GROUP

Douglas McDougall  
OISE/University of Toronto  
dmcdougall@oise.utoronto.ca

Jean J. McGehee  
University of Central  
Arkansas  
jeanm@mail.uca.edu

Keith Leatham  
Portland State University  
kleatham@pth.pdx.edu

The working group on Geometry and Technology has met since the PME-NA XX conference at Raleigh, North Carolina in 1998. The objectives were to explore: the technology environment, student perspectives, and teacher perspectives. Since this initial year, we have discussed

- The student in an environment created and caused by micro worlds (PME-NA XXI)
- Preservice teachers' understanding about the role of proof in mathematics and the impact of dynamic geometry software on their understanding of proof and proof-writing skills (PME-NA XXII),
- A focus on proof with the investigations of the role of software in moving students from conjectures about drawings to the theoretical work with sketches (PME-NA XXIII)

Correspondence with the network established in the working group indicated that participants in 2001 wanted to continue sharing instruments and methods from ongoing projects. Instead of organizing the group sessions as a set of presentations, the group leaders used the network's suggestion to develop a format that would require participants to actively work on instruments and discuss potential student responses that would be meaningful to research. They presented two tasks from the Balanced Assessment Project and used *Rethinking Proof* (de Villiers, 1999) as a model for developing new performance tasks in research.

The group leaders divided participants into small groups and asked each group to discuss the mathematics in each Balanced Assessment task and to examine sample student responses. The essential parts of a high school level task involving properties of circles is shown below:

The circular glass top of your neighbor's coffee table breaks. Your neighbor is very upset and would like to replace the glass top but does not know exactly how big it was. He brings you a piece of broken glass that contains part of the boundary of the original top. Describe exactly what you would do in order to figure out the exact size of the original glass tabletop.

Figure 1. Task 1: Glass Top.

Students who attempt this problem know that a center and a circumference point determine a circle, and in this case the center is missing. A typical student response is to extend the outer straight edges of the glass piece and to mark the intersection as the center of the circle. Another student response shows that the student estimated that the arc of the glass piece was  $\frac{1}{4}$  of the circumference. If the length of the arc is measured, the circumference and subsequently the diameter measure can be determined so that the full glass circle can be ordered. Some students remember that chords are somehow used to find the center of the circle but do not recall using the perpendicular bisectors of the chords to find the center. The first two students used an eyeball estimate to propose a solution. They used a method to produce a circle that looked good enough but did not check this solution for accuracy. The third student vaguely remembered some properties of a circle, but her memory of the logical relationships among the circle, chords, and the center was incomplete.

These responses demonstrate the struggle students have because they separate activities such as application and drawing from proof and reasoning. Schoenfeld (1986) describes students as “naïve empiricists whose approach to straightedge-and-compass constructions is an empirical guess-and test-loop” (p. 242). In proof, the objects are hypothetical and theoretical; the standard of correctness for the student is logic. On the other hand, objects in constructions and diagrams have spatial-graphical properties and are real; the standard of correctness is accuracy of the drawing.

Theoretically, geometry software should address the gap between empirical work and deductive thought because the dynamic features of the software make it a philosophical tool that allows spatial-graphical diagrams to behave in a theoretical way. The group leaders posed these questions:

1. How would students perform differently if this task were in a computer environment?
2. Do students demonstrate the use of deductive thought with the software as a philosophical tool?

An obvious response was that students could more easily check their solutions to see if the proposed circle fit the curve of the glass. However, checking is still empirical work. It was noted that students could cheat by selecting three points on the given arc in a certain order to draw the major arc and complete the circle. While this response demonstrates knowledge of the software, the student may not know the theoretical relationships to find the center. It was noted that very different and interesting solutions could be found that student would probably not attempt with pencil and paper.

A second task involved the properties of quadrilaterals and measurement calculations (See Figure 2). The working group liked this task because it encompassed a wide variety of geometric topics. It requires students:

- To use spatial reasoning with properties of the rectangle and rhombus to explain why most envelopes make a rhombus when unfolded.

You work for an envelope manufacturer. You have been given a job by your boss: investigate different envelopes that will hold this invitation. There will be three parts to this investigation:

1. Explain why most envelopes make a rhombus when they are unfolded.
2. Design a "rhombus" envelope to fit the card giving all measurements of sides and angles.
3. Design an envelope to fit the card that makes a rectangle when it is unfolded and give the measurements of the sides and marked angles.

Note: Diagrams on two more pages of the task suggested the geometry involved for students in this task.

Figure 3. Task 2: Design an Envelope.

- To use the Pythagorean theorem and trigonometric ratios to design an envelope and provide measurements.
- To use similarity and/or trigonometry to design an envelope that makes a rectangle when it is unfolded.

In a computer environment students could find points A, B, C, and D by using reflections over the edges of the invitation. Of course students could cheat with the mea-

surement tool, but they could be required to justify the measurements. The following samples show student work:

Student A: "ABCD is a rhombus because it is a sloping square."

Student B: He/she used the Pythagorean theorem appropriately to calculate the side measurements of the rhombus but believed that the diagonals of the rectangular invitation bisected the right angles. He/she also knew that the triangle formed with the rectangular envelope were similar but could not proceed to make calculations with ratios.

Student C: "The diagonals of a rectangle bisect each other, and the endpoints of the diagonals form the midpoints of the sides of the outershape. Since all of the segments formed by the midpoints are congruent, the outer figure is a rhombus." This student also used the Pythagorean theorem appropriately and recognized the similar triangles in the rectangular envelop without calculating the measurements.

Student D: This student did not have as nice an explanation as student C for the rhombus figure, but he/she did systematically and accurately perform all measurement calculations.

The computer software would have allowed students to test statements and measurements. For example, Student B could have tested the conjecture about angle measure. A more interesting and appropriate task for the computer would be to require students to construct the envelopes without showing them the unfolded diagrams.

After the discussion of these Balanced Assessment tasks, the group leaders introduced the article *Rethinking Proof* (de Villiers, 1999). De Villiers relates students' separation of application and drawing from proof and reasoning to van Hiele theory. He emphasizes *constructive defining*, a process in which concepts and theory are constructed by "changing a given definition by excluding, generalizing, specializing, replacing, or adding properties to the definition." (p. 15) This process progresses through the van Hiele levels. At level 1 students use visual definitions and recognize whole figures; at level 2 they use uneconomical definitions, recognizing all properties for a given figure; and at level 3 they use correct, economical definitions and recognize logical relationships between figures; level 4 students use longer sequences of logical statements and recognize a system of definitions, axioms, and theorems. Levels 1 and 2 students also have partitional definitions as opposed to the level 3 hierarchical definitions that allow inclusion of subsets of figures in more general sets of figures (squares are subsets of rectangles). De Villiers states that teachers should allow students to construct and refine definitions at all levels. He demonstrates how the dynamic nature of software can aid in the development of hierarchical definitions and advocates that teachers first provide ready-made constructions of figures so that properties can be thoroughly explored in the causal relationship between a premise condition and a

conclusion. For example, “perpendicular bisecting diagonals” is a consequence of constructing “all four sides equal” in a quadrilateral. “A tangent line at a point on a circle” is a consequence of constructing “the perpendicular to the radius determined by that point.” Eventually students learn to make their own constructions. Citing an older but nonetheless relevant article, Smith (1940), de Villiers describes the importance of using “if-then” thinking in learning to do constructions:

Pupils saw that when they did certain things in making a figure, certain other things resulted. They learned to feel the difference in category between the relationships they *put* into a figure—the things over which they had control—and the relationships which *resulted* without any action on their part. Finally the difference in these two categories was associated with the difference between the *given* conditions and *conclusions*, between the if-part and the then-part of a sentence.

The computer environment allows students to explore which properties or conditions are necessary for a construction and to reduce the properties until they have a sufficient set for construction. When a sketch is created with logical properties that students *put* into a figure, other relationships *result and remain* invariant when the students drag the defining objects of the sketch. It would seem that the students who responded to the Glass Top task missed the prerequisite experiences of exploring the logical relationships among radii, chords, tangents, and perpendicular lines. Without a known center, only general chords could be constructed in the glass piece. Perpendicular bisectors of chords necessarily contain the circle center, and two intersecting perpendicular bisectors are sufficient to determine the center point. The task itself could be done with or without the computer, but perhaps the conceptual substructure needs to be developed with the geometry software.

Because the logical “if-then” syntax is integral to geometry software and should provide a connection between drawing and proof, the group leaders extended the work with Balanced Assessment tasks to de Villiers’ activities categorized by functions of proof. In *Rethinking Proof*, de Villiers (1999) has listed these functions of proof:

- Verification (concerned with the truth of a statement)
- Explanation (providing insight into why it is true)
- Systematization (the organization of various results into a deductive system of axioms, major concepts and theorems)
- Discovery (the discovery or invention of new results)
- Communication (the transmission of mathematical knowledge). (p. 4)
- Intellectual challenge (the self-realization/fulfillment derived from constructing a proof)

De Villiers' research (1991) indicates that explanation, discovery, and verification can be meaningful to level 2 students while challenge and systematization are appropriate for level 3 and 4 students. If students have experiences with the first three functions, teachers help them make a transition from level 2 to levels 3 and 4. This result opens investigations to study samples from the middle grades (5-8) to college level.

The working group leaders assigned each of 6 small groups one of these functions of proof so that fertile ideas could be developed for any convenient sample of study and new performance tasks for research could be modeled. Each group described deVilliers' interpretation of this function, added a group opinion, and reported an example of a task that would demonstrate this role. The following summaries review the group reports:

*Group 1-Verification:* A convincing argument bolsters the conviction that a conjecture is true. Testing whether or not a conjecture makes sense and fits with other logical relationships and properties is an important aspect of mathematical activity. In one example, "Area," (de Villiers, 1999, p. 73) students are given a pre-made sketch of the following quadrilateral. They are asked to make a conjecture about the relationships between the area of IJKL and ABCD. Of course, students will most likely use measurement tools to investigate, but the figure on the right provides a way for students to be convinced that the dissection actually divides the original figure into four equal areas.

Figure 3. Area comparison of quadrilaterals.

Making the figure on the right requires transformations and is more rigorous than testing with measurements.

*Group 2-Explanation:* Accurate constructions and measurements confirm a conjecture but do not explain why it is true; they are convincing but do not provide insight into how the conjecture fits with other familiar results. For example, a visual proof that the triangle sum of angles is  $180^\circ$  occurs when the angles are cut out and placed on a straight line. However, the proof provides insight into the necessity of the parallel postulate to establish the

relationship. This group also examined the concurrency of the medians at the centroid of a triangle. Dynamic software provides a convincing demonstration of the validity of the conjecture. The group showed how de Villiers' activity, "The Center of Gravity of a Triangle," (1999, p. 51) guides students to form a proof that explains the result with the use of auxiliary constructions, the midpoint connector theorem, and the properties of parallelograms. Students also gain insight into the technique of using the intersection of two segments to show that a third segment determined by this intersection and a triangle vertex also has the properties of the first two segments, namely that it is a median also.

*Group 3- Systematization:* Tasks that investigate systematization use properties that students have previously studied. They are not designed to determine whether these properties are true or not, but to investigate their underlying logical relationships. Students develop an understanding of the role of definitions in an axiomatic system and investigate alternative but equivalent definitions. Student definitions become both economical and hierarchical. An example studied by this group was "Systematizing Rhombus Properties." (de Villiers, 1999, p. 133)

*Group 4-Discovery:* Empirical work can lead to discovery of logical relationships when students participate in the explore/discover/conjecture/prove model of teaching geometry. However, some results can be discovered in a deductive manner, i.e. proof may lead to proof. When writing a proof, one may realize that the argument can be modified somehow to lead to other relationships and conclusions, and hence, other proofs. This group shared the example of how students can discover the law of cosines in the process of exploring chord relationships in a circle using geometry software. A participant showed how the theorem, "If two chords intersect in the interior of a circle, then the product of the measures of the segments of one chord is equal to the product of the measures of the segments of the other chord." leads to the law of cosines. The group also discussed the value of having students investigate false conjectures in order to underscore the idea that a valuable part of exploration is the search for counterexamples. Consider: Given a rectangle, the area increases as the perimeter increases. Finding and characterizing counterexamples of this statement show why a proof of the conjecture is impossible.

*Group 5-Communication:* Both the "internal" communication required when one is thinking through a problem and the "external" communication required to share work with others encompasses all the roles of proof. The group agreed with de Villiers (1999, p. 7) that proof is a form of social interaction and involves negotiating both the meaning of mathematical concepts and the

criteria for acceptable argument. However, they questioned isolating this role of proof in tasks because any task that could isolate use of any of the other roles would necessarily demonstrate communication skills. In fact, de Villiers does not develop separate activities for this role.

*Group 6-Intellectual Challenge:* Sometimes we seek to prove a conjecture simply because it is there to be proved. The Pythagorean theorem is perfect example for thinking about proof in this way. Although one proof was certainly sufficient, there exist hundreds of proofs of this famous relationship. The challenge might be to find a proof that is more elegant more intuitive, or more direct. Proof as intellectual challenge also includes the mathematical activity of extension—changing initial conditions, removing or adding constraints, asking “what-if” questions and thinking outside of the box. This group shared an example of student work from a summer workshop in which inservice teachers explored proofs of the Pythagorean theorem and then extrapolated variations involving equilateral triangles and semi-circles on the sides of the right triangle. They also showed how teachers extended their investigations by connecting the vertices of the squares on the sides of the right triangle to form three new triangles that each have the same area as the original right triangle. In this manner, experimenting with a well-known proof provided opportunity to explore then make and prove other conjectures. The proof itself served to stimulate further mathematical activity and proof.

Figure 4. Inservice teacher extension of the Pythagorean theorem.

The culminating questions that occurred to several participants were, "How will students benefit from computer tasks that focus on the functions of proof?" and "Will these tasks transfer to design tasks so that students apply more theory to constructions?" The group leaders' charge to the working group participants was to investigate these questions by using an existing or developed assessment with a targeted group and report in 2002.

In addition to participant reports, the working group for PME-NA XXV will focus on an underlying theme in de Villiers' work, the idea of making sense of geometry through verification, explanation, discovery, and systematization. A key reading for this working group session will be "Sense Making: Changing the Game Played in the Typical Classroom." (Flewelling, 2002). On the first day, the group will briefly summarize past work and call for participant reports. We will review the new article and relate it to past work and tasks. Student learning in elementary levels through college geometry will be the focus of the second day. Participants will create and share sense-making tasks for various levels of students and discuss the implications such tasks/activities have for research. On the third day, we will discuss how the tasks/activities might differ in design for preservice and inservice teachers when there are both mathematical and pedagogical learning objectives. Working group participants will be encouraged to find ways to use the tasks/activities in their research and teaching over the coming year.

**INVESTIGATING AND ENHANCING THE DEVELOPMENT  
OF ALGEBRAIC REASONING IN THE EARLY GRADES  
(K-8): THE EARLY ALGEBRA WORKING GROUP**

**Coordinated by**

John Olive  
University of Georgia  
jolive@coe.uga.edu

Andrew Izsák  
University of Georgia  
izsak@coe.uga.edu

Maria Blanton  
University of Massachu-  
setts Dartmouth  
mblanton@uMassd.Edu

The Early Algebra Working Group is interested in investigating and enhancing the development of algebraic reasoning in young children, primarily in grades K-8. The group is NOT interested in investigating or promoting the *early* introduction of the standard high-school algebra course in the elementary or middle grades. Our focus is on investigating and describing what we construe as the possible geneses of algebraic reasoning in young children, and in developing and investigating ways to enhance that reasoning through innovative instruction, applications of appropriate technology and professional development for teachers.

**Brief History of the Group**

The Early Algebra Group (EARG) has been meeting since 1998 and, more recently, in response to a call from the International Commission on Mathematical Instruction (ICMI), constituted the Early Algebra Working Group (EAWG), one of the eight groups in the 12<sup>th</sup> ICMI Study Conference *The Future of the Teaching and Learning of Algebra* (Chick, Stacey, Vincent & Vincent, 2001) held in Melbourne, Australia, in December of 2001. The EAWG held a preparatory meeting before the Melbourne Conference and conducted an email discussion of points to be raised at the conference. During the conference, the EAWG met for a total of 14 hours over 5 days. A report was given to the whole conference that summarized the results of our discussions. This report outlined the following points:

1. What Early Algebra is NOT (it is not the early introduction of standard HS algebra).
2. Historical overview (the different origins of arithmetic and algebra).
3. Overview of research in Early Algebra (from 1970's through present day with some concrete illustrations using video clips from various research projects).
4. Implications of this research for algebra in grades 6-14.
5. Work to be done: Research and Policy Issues needing attention.

### Plans for Sessions at PME-NA

During the PME-NA meeting we plan to hold at least three sessions (one on each of Sunday, Monday and Tuesday). The opening session will begin with a report from the ICMI EAWG discussions that will provide an overview and vision for the Working Group and share the conclusions of the ICMI EAWG with the wider PME-NA community. Jim Kaput will lead this overview. We shall invite discussion of these conclusions and outline the goals for the rest of the sessions. Les Steffe and Andrew Izsak will make brief presentations on their proposed research on students' quantitative reasoning and how this relates to students' algebraic development. At the Monday session, Analúcia Schliemann will present results from the TERC/Tufts longitudinal study on early algebra in 2<sup>nd</sup> through 4<sup>th</sup>-grade classrooms, Teresa Rojano will present her research on an early approach to functions using computing technologies and Joanne Lobato will present a report on her research concerned with transfer and generalization in the context of quantitative reasoning. The final session on Tuesday will begin with a report from Megan Franke on the work of the *National Center for Improving Student Learning and Achievement in Mathematics and Science* on issues related to the professional development for elementary teachers with respect to algebraic thinking. We shall end the session with a discussion of the issues raised during the meetings of the WG at the conference and plans for future activities, including discussion group meetings at PME 27 in Hawaii.

Brief papers describing each of the scheduled presentations follow this introduction.

### RESEARCH ON THE DEVELOPMENT OF ALGEBRAIC REASONING IN THE CONTEXT OF ELEMENTARY MATHEMATICS: A BRIEF HISTORICAL OVERVIEW

James Kaput  
University of Massachusetts-Dartmouth  
jkaput@umassd.edu

### The Algebra Problem

The US has an increasingly difficult "Algebra Problem" to solve. Standard indicators of student achievement – international comparisons, NAEP and other national

measures, as well as state test results—all point to decreasing achievement as grade levels increase. Well-known TIMSS curricular analyses point towards repetitious computational skill building and superficiality of topic coverage as important contributors to the problem. The repetition is followed by a delayed, abrupt and isolated first year algebra course, with continued tell-and-drill pedagogy that puts students in an overly passive position as learners. High failure rates in first year algebra courses, especially in urban districts, contribute to student alienation, high drop-out rates, and low teacher morale. Increasingly political responses to the problem involve a wide variety, but largely ineffective tactics in the form of middle and early high school pre-algebra courses of various kinds, screening and diagnostic tests, district and state algebra mandates, lengthened courses, diluting the definition of “algebra,” creating multiple versions of “algebra,” end-of-course & other high-stakes exams, among others. Each adjustment produces small local improvements, although, since the tactics tend to be ad hoc and implemented independently, improvements do not accumulate or multiply. NCTM recommendations for integrating the development of algebraic reasoning across K-12 are implemented only in a few of the standards-based curricula, and these mainly at the middle school level. And most importantly, algebra’s breadth & depth are not systematically reflected in school mathematics experience, so that School Algebra does not serve School Mathematics in the positive ways that Algebra has historically served Mathematics.

### **Research Toward Solutions**

Several research teams studying the development of algebraic reasoning in the early (K-5) grades formed an informal research collaborative in the late 90’s which renews a prior collaboration funded by the US DoE OERI in the early/mid 1990’s through the National Center for Research in Mathematical Sciences Education that in turn grew out of an earlier “Algebra Working Group” in the latter 1980’s that examined the nature and purposes of algebra in school mathematics. Today’s line of work shares broad hypotheses regarding the large positive potential of building algebraic reasoning in the context of elementary mathematics, the need to exploit untapped student learning capacities among younger students, the powerful role of generalization and formalization in deepening students’ experience and understanding of elementary mathematics – especially arithmetic—and the potential for using changes in the curricular relationships between algebra and elementary mathematics as a catalyst and vehicle for faculty development of elementary teachers. These researchers engage in several complementary lines of work focusing on different aspects of the problem—student learning, classroom practice, curriculum design, professional development, capacity building, and so on.

### **Reflections on Why the Algebra Problem Is Difficult**

Several aspects of the problem contribute to its depth and complexity beyond uncertainty regarding its place in the curriculum or its relevance and importance due to

continuing changes in technology and applications. We see 2 categories of reasons: (a) involving the inherent complexity of algebra content, and (b) institutional/historical reasons.

### **Content Reasons:**

The pervasiveness of the roots of and uses of algebraic reasoning mean that it is not just a topic or topic strand. It has multiple interacting aspects, two of which underlie the others. Root Aspect #1: Algebra as generalizing and systematically expressing patterns & constraints, especially, but not exclusively, algebra as generalized arithmetic & quantitative reasoning. Embodying generality and the systematic expression of generality, it is an intrinsic way of being mathematical. Root Aspect #2: Algebra as reasoning from the *forms* of syntactically-defined statements and the syntactically guided manipulation of those formalisms to build insight. Other aspects of algebra, include algebra as the study of patterns, functions & relations, as the study of the structure of operations & systems (abstract algebra), and algebra as a web of representation systems.

### **Institutional/Historical Reasons:**

School algebra is hard to change because: (1) Algebra is a Socio-Political-Economic Institution as well as a web of skill & knowledge that complexly interact with other knowledge & skill. (2) Algebra the Institution co-evolved with our systems of education, so is deeply intertwined with them and cannot change independently of them. (3) Algebra & arithmetic had different historical origins, served different social purposes, served different populations and were historically instantiated as separate curricula for demographically separate populations.

## **THE ONTOGENESIS OF ALGEBRAIC KNOWLEDGE**

Leslie P. Steffe, John Olive, Amy Hackenberg, & Brian Lawler  
University of Georgia  
lsteffe@coe.uga.edu

Mathematics education as a profession is in a period of reform to improve the teaching and learning of school algebra. Furthermore, “algebra for all” is a popular mandate in schools and mathematics education policy documents that signals desires for and movement toward more equitable school practices. However, without rethinking what algebraic reasoning is and how students learn to reason algebraically, these mandates effectively legislate that everyone must come to know a univocal algebra that the researchers feel does not necessarily respect individuals’ ways of knowing and does not necessarily delve deeply into conceptual ways and means of operating algebraically. Interpretation of “algebra for all” mandates within the reform movement

is crucial because our prior research (Olive, 1999; Steffe, 2002; Steffe & Olive, 1998) indicates that students come to middle school with distinctly different ways of operating quantitatively and numerically, ways that we believe will significantly impact the students' development of algebraic knowing.

Thus, to interpret such mandates, we plan to conduct an ontogenetic analysis of algebraic knowing by examining how 6<sup>th</sup> and 7<sup>th</sup> grade students operate quantitatively and by investigating how to bring forth their algebraic reasoning as a reconstitution of their quantitative operating. Based on prior research on children's number sequences (Steffe & Cobb, 1988; Steffe, 1992) and children's fractional knowledge (Steffe & Olive, 1998) we have identified three categories of students that are fundamental to this work: *pre-fractional* students, *additive fractional* students, and *reciprocal reasoners*. Students in the different categories reason in significantly different ways: pre-fractional and additive fractional students are yet to construct multiplicative fractional concepts. Since quantitative and numerical operating forms a basis for algebraic reasoning, the nature of the quantitative operating of these students presents a serious and as yet unsolved problem in mathematics education. While reciprocal reasoners operate multiplicatively, many have not yet constructed fractional operations that are fundamental to reasoning algebraically. The goal of this research is to construct an algebraic learning trajectory for each of these categories of students based on their initial concepts and operations and how these concepts and operations are used in their further constructive activity. An ontogenetic analysis is made as we construct actual learning trajectories of students using hypothetical learning trajectories as a guide in the process of teaching students. Thus, an essential orientation in this research is to bring forth students' algebraic reasoning out of their quantitative operating in the context of teaching-learning interactions. We hypothesize that the pre-fractional and additive fractional students will make progress toward constructing an additive algebra, including unknowns and equations, as well as multiplicative operations and ratios. Once the reciprocal reasoners have constructed fractional operations, they will move toward the construction of rates, variables, covariation, and linear functions.

We plan to conduct a three-year constructivist teaching experiment with four students in each of the three categories starting in the spring semester of the students' 6<sup>th</sup> Grade and working with them twice a week over the course of two years. As we use teaching as a source of scientific investigation, our intention is to teach the students with the goal of promoting the greatest possible progress we can in all of the participating students. To this end and to serve our central goal, we formulate and test local hypotheses within teaching episodes. The work of the teaching experiment will include: ongoing conceptual analysis of quantity, quantitative operations, and algebraic knowing; a mapping of actual learning trajectories based on hypothetical learning trajectories; and extensive use of representations and technology tools.

### COORDINATING STUDENTS' AND TEACHERS' ALGEBRAIC REASONING (COSTAR)

Andrew Izsák, Brad Findell, John Olive, & Chandra Orrill  
University of Georgia  
izsak@coe.uga.edu

Student learning in algebra is a perennial concern in U.S. mathematics education. In recent international studies, U.S. middle-school students' achievement in algebra lagged behind that of their peers in high-achieving countries (National Center for Education Statistics, 2001b; Peak, 1996). Despite increases in average scores on the National Assessment of Educational Progress (NAEP) exam in 2000, 34% of the nation's eighth graders scored below a "basic" level of performance in mathematics (National Center for Education Statistics, 2001a). Moreover, improving the teaching and learning of school algebra in the United States has become central to achieving equity in mathematics education because difficulties with algebra can constrain students' career choices and perspectives on the surrounding world. In response to claims that algebra predicts success in college, there have been recent calls for "algebra for all."

Alternative responses to the algebra problem take into account expanded notions of what school algebra can be, similar to those articulated by Kaput (1995), National Council of Teachers of Mathematics's (NCTM) *Principles and Standards for School Mathematics* (2000), and the National Research Council (NRC) (Kilpatrick, Swafford, & Findell, 2001). For example, the NRC committee characterized algebra as consisting of: *Representational* activities, *transformational* activities (i.e., operating on and transforming algebraic symbols), and *generalizing and justifying* activities. Some versions of an expanded algebra are more explicit about algebraic structure and relations among operations. All versions stress that algebra includes not only operating on and transforming algebraic symbols but also ways of representing and reasoning about problem situations that contain features such as *unknowns*, *patterns*, and *covariation*.

Expanded notions of algebra have set the stage not only for changing high-school algebra courses but also for instructional approaches intended to make important aspects of algebra accessible to younger students. The NSF has supported the development of middle-school materials and high-school materials that are aligned with the NCTM *Standards*, but the NRC (Kilpatrick et al., 2001, p. 279) has pointed out that more research is needed on the role that expanded activities can play in the development of “symbol sense.” The proposed work is an instance of such research in the context of an expanded algebra. In particular, the mathematical content at the center of our proposed research lies at the intersection of algebra, problem solving, and representations.

**Algebra.** We start with a general characterization of algebra that is consistent with that articulated by the NRC. That is, we take algebra to be a subject concerned not only with operating on and transforming algebraic symbols but also with representing and solving problems, generalizing and justifying arguments, and reasoning about relations among operations. We focus on multiplicative comparisons—including ratio, rate, and slope—in problem situations that contain unknown quantities, patterns, or covariation.

**Problem solving.** We ground our perspective on problem solving in those perspectives previously developed. Schoenfeld (1992) summarized five aspects of mathematical thinking and problem solving around which there is considerable agreement: (1) The knowledge base, (2) Problem-solving strategies, (3) Monitoring and control, (4) Beliefs and affects, and (5) Practices. A mathematical task is a problem only when it is not routine for the person trying to accomplish that task; that is, when the person cannot quickly generate a path by which to complete the task. In particular, we take algebra problem solving to be neither the routine manipulation of symbols—although such activities can play an important role in algebra problem solving—nor the solution of routine word problems.

**Representations.** Considerable theoretical and empirical work has been done in mathematics and science education on both internal and external representations. We use the word “representation” to refer to external ones. Empirical work has made clear that students often struggle to understand and use standard mathematical representations found in algebra courses to solve problems (e.g., Kieran, 1992). Some recent research has focused on how students can construct their own representations to successfully solve problems about physical situations with algebra (e.g., Izsák, 2000, in press).

The proposed research will focus on teachers’ and students’ understandings of shared classroom interactions and on ways that teachers and students work together to shape the teaching and learning of middle-school algebra through representing and solving problems. To gain access to and analyze teachers’ and students’ understand-

ings of shared classroom interactions, the project will coordinate analyses of taken-as-shared classroom problem-solving practices with individual teachers' and students' understandings of those practices. Thus, the project will examine the sense that students make of their opportunities to learn and teachers' sensitivity to the core learning issues for their students.

## FROM UNKNOWN AMOUNTS TO REPRESENTING VARIABLES

Analúcia D. Schliemann  
Tufts University  
aschliem@tufts.edu

David Carraher  
TERC  
david\_carraher@terc.edu

Barbara M. Brizuela  
Tufts University  
barbara.brizuela@tufts.edu

Our work in Early Algebra has been built on the ideas that (a) generalizing lies at the heart of algebraic reasoning; (b) arithmetical operations can be viewed as functions; and (c) students' spontaneous representations of mathematical relations can be nurtured to evolve into meaningful notation based on mathematical conventions. We have also assumed that mathematical learning is an inherently social activity, closely tied to the discussions and contexts where it takes place. We will illustrate how such cognitive and social ideas underpin the design and implementation of third grade algebraic-arithmetic tasks related to the operations of addition and subtraction.

In planning the lesson we will describe, we had several specific considerations in mind, among which were the following:

1. Additive comparisons tended to be somewhat challenging to third graders;
2. Although the amount in each box was unspecified, the difference was fixed; from earlier work, we knew that a difference quantity is an important component of additive structures;
3. We wondered whether and how children would express the idea that there could be many possible values for two compared amounts;
4. The problem would possibly provide an opportunity to introduce letters to stand for unknown amounts and for variables; and
5. The activity would best be promoted through intellectually playful dialogue in a setting where students were encouraged to express their ideas and show their insightfulness into the problem.

Our example is part of our second to fourth grade longitudinal investigation with the students of four classrooms in a public elementary school from a multi-cultural working-class community in Greater Boston. Descriptions of our class materials are available at [www.earlyalgebra.terc.edu](http://www.earlyalgebra.terc.edu). The lesson we focus upon in this paper was the first one we taught to third grade students we had been working with since second grade.

The lesson is structured around a situation in which one child, Mary, is said to have three more candies than another child, John. We actually show two boxes, one Mary's, the other John's, and assert that there are equal amounts of candies in each. We then take an additional three candies and place them on top of Mary's box and state that her total amount includes both the candies inside and on top of the box. We begin by asking the students to express what they know about John and Mary's amounts.

The problem can be viewed both as a particular empirical state of affairs and as a set of logical possibilities. The former viewpoint gains prominence when one wonders how many candies are actually in the box. The latter emerges as one focuses on the verbal description of the problem and attempts to find multiple “solutions”. Each viewpoint offers its version of truth or correctness. There can only be one empirical truth regarding the number of candies John and Mary have. By this standard, only students who guess the numbers of candies in the boxes can be right. However, the logical standard accepts all answers consistent with the information given, regardless of whether they correspond to the reality present in the classroom. As one student expressed it, “Everybody [in her class] had the right answer... Because everybody... has three more. Always.” This second viewpoint supports the idea of a variable: there are multiple possibilities that would make the basic premise of the problem true.

By asking the students to make predictions about numbers of candies, we may have encouraged some of them to construe their task as having to guess accurately. However, this served as an opportunity to discuss “impossible answers”, such as the suggestion that one child had 8 candies and the other 10 candies. These answers are of course “impossible” only by virtue of the verbal information provided. Furthermore, once the prediction table was set up, students could try to describe what features were invariant among the (valid) answers. In a sense, the data table allowed students to make a generalization.

The mere fact that they entertained an expression such as “ $N+3$ ” as a reasonable way to express Mary’s candies as a function of John’s was encouraging. We believe students accepted this because the notation was a natural extension to the students’ own experience. One student had introduced question marks to represent John and Mary’s amounts. This led the teacher-researcher to point out the potential confusion due to using the same symbol, “?”, to represent different amounts. This puzzle was advanced when students suggested that Mary’s amount should be “any number plus three”, which the teacher embodied first as “ $? + 3$ ” and later as “ $N+3$ ”.

Another teacher-researcher outright proposed that students adopt the letter  $N$  to specify an unknown amount. Once the students accepted this convention they came to the conclusion, through suggestions by two of the students, that Mary’s amount should be called “ $N$  plus three.” This is admittedly a small step in the direction of using algebraic notation; but we consider it an important one.

The second day of the candies activity took the discussion further into the territory of logical possibilities and constraints. In this class we asked the students to consider the totals of John’s and Mary’s candies, given the “fact” that Mary had three more candies than John. Could they have 15 candies, together? What about 12 candies? Or 2 candies? Why or why not? We gave them a number of problems to figure out based on varying assumptions about the totals. After working through several of these examples (with odd numbered totals), they began to see that there was a pattern: they

could determine the number of candies in each box systematically. However, the fact that students systematically solved the problem (subtracting 3 and dividing the result by 2) did not guarantee that they could state their procedures clearly: at least two pairs of students in one class described their approach as dividing by 2 *and then* subtracting 3. Eventually, we would like to have seen them produce answers such as  $(N-3)/2$ , but they would need considerably more experience with using letters to stand for unknown amounts before such an expression would make sense to them.

### **AN EARLY APPROACH TO FUNCTIONS: THE MEDIATING ROLE OF COMPUTER-BASED ALGEBRA-LIKE SIGN SYSTEM**

Teresa Rojano  
CINVESTAV, Mexico  
trojano@mail.cinvestav.mx

Conceiving that the simultaneous variation of two variables in a numeric function table is governed by a general rule is an idea that many secondary pupils find very difficult. Even more difficult they find the idea that such variation can be analyzed and “manipulated” through expressing the corresponding rule in a symbolic (algebraic) way. The latter presupposes an appropriate understanding of numeric substitution in a formula as well as a basic notion of numeric variation domains. This means that from the perspective of the symbolic algebra, the mathematical sign system of algebra plays a crucial role as a mediator of subject’s action, to build up the concept of functional variation. In some previous studies, this role of the notation system has been seen more as a constraint for pupils’ thinking, rather than as a thought mediator.

However, in other studies, there has been gathered evidence with regards how algebra-like sign systems like spreadsheets can help 10-15 year olds to express and manipulate a functional relationship (Rojano & Sutherland, 1994). Results of this sort suggest that when working with a spreadsheet, children can resort to their numeric knowledge at the same time that they have to deal with a language that captures the generality of variation and functional dependence. This can be interpreted in the sense that the spreadsheet language takes on a mediating role in the pupils’ development of an algebraic notion of function.

Cases from the spreadsheets study mentioned above corresponding to the youngest pupils (10 year olds) can be used as examples of how an early introduction to algebraic thinking can take place through a numeric grounded approach to functions. Whereas, issues from the same study with “algebra resistant pupils” (of 15 years of age) suggest that a connection between spreadsheets language and the algebraic code is feasible. In this way, a possible rout to algebra can be conceived, in which algebraic symbolism can be recovered as the language of generality and variation in school mathematics. Issues arising from a couple of cases will be used in this presentation to illustrate

how this can be possible. A reference to Balacheff's paper on "symbolic arithmetic" (Balacheff, 2001) and to Filloy's work on transitional processes from arithmetic to algebra (Filloy, Rojano, & Rubio, 2001) will be made, in order to provide a framework for discussion about the nature of the mathematical thinking that is produced by experiencing variation in a spreadsheet environment. In a recent publication, Yerushalmy and Chazan bring in an analysis of the use of multiple representations of functions in technologically supported approaches to introductory algebra (Yerushalmy & Chazan, 2002). These authors emphasize the influence that such a multi-representational treatment has had in the curricular role of functions in school algebra. This perspective could enrich our discussion, in terms of implications for the algebra curriculum.

### RETHINKING TRANSFER AND GENERALIZATION IN THE CONTEXT OF QUANTITATIVE REASONING

Joanne Lobato  
San Diego State University  
lobato@saturn.sdsu.edu

Two issues will be explored in this presentation—one involving generalization activities in algebra and the second involving a reconceived view of transfer that emerged from studies of algebraic thinking. Quantitative reasoning plays a critical role in each of these explorations. According to Thompson (1994), quantitative reasoning

involves the construction of new quantities and relationships among quantities in a situation, where a quantity refers to one's conception of measurable attributes of objects, such as height or distance. Quantitative is not a synonym for numeric, as the term is often used in statistics; quantitative reasoning can be nonnumeric in nature. The two themes in this presentation are also informed by empirical studies conducted as part of a continuing 5-year research project, the Generalization of Learning Mathematics in Multimedia Environments. One of the major goals of the project is to examine how instruction based on quantitative reasoning about ratios, rates of change, and linear functions affects the nature of individual students' generalizations when reasoning about novel "real world" situations (such as wheelchair ramps, speed, and heart rates). Although the studies have been conducted with middle and high school students, many of the findings are applicable to discussions of early algebra.

Many researchers have argued that the development of generalization and the systematic expression of generality are key elements in distinguishing algebraic from arithmetic activity (e.g., Bednarz, Kieran, & Lee, 1996). However, the generalization activities in reform mathematics materials typically involve the generalization of number patterns. Lobato and her colleagues demonstrate the limitations of generalizing based on numeric patterns alone and the importance of generalizing based upon quantitative reasoning (Lobato & Ellis, in press; Lobato & Thanheiser, 2002). Specifically, they investigated students' reasoning in a modified *SimCalc Mathworlds* computer environment (1996), in which students entered distance and time values for one animated character so that the character would walk the same speed as a given character. Students generalized numeric patterns, for example noting that multiplying both distance and time values by the same number will produce "same speed" values. However, closer investigation revealed that students could not explain why the patterns worked. Furthermore, they produced visual representations that failed to capture the proportional nature of the situation. In contrast, the classroom discussion encouraged students to develop a justification for why doubling both time and distance did not change the speed, which was based upon reasoning with the quantities in the situation—distance, time, and speed—rather than based solely upon numeric reasoning. As a result, students demonstrated evidence of constructing ratios as a measure of speed, which appeared to lead to more powerful generalizations than did the numeric reasoning. This finding suggests a number of questions to be explored in the session: (a) How might justifications that rely upon quantitative reasoning differ given a variety of phenomenologies, such as a heart rate situation rather than speed situation?; (b) Is there a common characteristic among justifications and generalizations that have a quantitative as opposed to a numeric basis?; and (c) How can teachers and technological environments support a focus on quantitative reasoning?

A second issue related to quantitative reasoning in algebra involves rethinking key aspects of the transfer construct, in particular the surface/structure distinction of traditional models of transfer. In transfer experiments researchers typically provide

subjects with paired tasks that share “structural” features, usually the same solution method, but differ in terms of “surface” features, usually the situational aspects of the word problem. For example, the two tasks of calculating the slope of a line and finding the slope of a wheelchair ramp are typically conceived as sharing the same structural or mathematical relationship between slope, “rise,” and “run,” but differing in terms of a graphical versus a “real world” context. At the heart of the structure/surface distinction is an assumption that the paired tasks share a similar level of complexity, but for whom—the researcher or the subjects? Researchers operating within a traditional model of transfer adopt an observer’s perspective since they predetermine what counts as transfer and what constitutes structural similarity between tasks using normative models of performance. In contrast, a reconceived model of transfer, called *actor-oriented transfer* (Lobato, 2002) will be presented. Actor-oriented transfer rests on a definition of transfer as the personal creation of relations of similarity, or how “actors” see situations as similar. One consequence of adapting an actor-oriented view of transfer is demonstrated by Lobato and Siebert’s (in press) work, which suggests that what researchers typically consider a surface feature can present conceptual complexities for students that are more structural in nature than previously understood. Specifically, Lobato and Siebert document how an eighth-grader was unable to “transfer” his understanding of the slope formula to a typical transfer task involving a wheelchair ramp, due to the quantitative complexity of the transfer situation. At the end of a teaching experiment, the researchers presented the student with the same wheelchair ramp situation again. Once the student reconstructed his understanding of the relationships among the quantities in the situation, he was able to provide evidence of actor-oriented transfer using previous proportional-reasoning experiences from the teaching experiment. This study provides some understanding of the types of quantitative reasoning that students need to develop in order to succeed in complex transfer situations. The work also raises important questions regarding how to provide instructional experiences that enable students to make sense of quantitatively complex situations without directly providing instruction related to each target situation.

### RETHINKING PROFESSIONAL DEVELOPMENT FOR ELEMENTARY SCHOOL TEACHERS AROUND ALGEBRAIC THINKING

Megan L. Franke, Thomas Carpenter, Dan Battey, Linda Levi, & Victoria Deneroff

A growing consensus suggests that it is necessary to reconceptualize the nature of algebra and algebraic reasoning and to provide students opportunity to engage in algebraic reasoning earlier in their education (Kaput, 1998; National Council of Teachers of Mathematics, 1997, 1998). The artificial separation of arithmetic and algebra traditional in school mathematics curricula deprives students of powerful schemes for thinking about mathematics in the early grades and makes it more difficult for them to learn algebra in the later grades (Kieran, 1992; Matz, 1982). For the last five years we have been working with teachers and students to understand how to create classroom environments that provide opportunities to engage in algebraic thinking. We have developed ways of thinking about both the content of algebraic thinking for the elementary school grades and how to provide support for teachers as they consider engaging their students in algebraic thinking.

Drawing on Robert Davis's (1964) seminal work on the Madison Project, we have used the solution and discussion of true, false, and open number as a primary context for helping teachers understand and focus on student thinking. These number sentences provide a context to initiate conversations that can lead to generalization and to introduce discussion of notation that might be used to express those generalizations. This context has proved particularly fruitful in engaging students in algebraic thinking and making that thinking visible to teachers. Specific ideas that we have addressed include: (a) equality as a relation, (b) generalization about number and properties of operations, (c) representation of generalizations, and (d) the progression of forms of argument that students use to justify generalizations. Previous research suggests that students in traditional classrooms are not aware of the underlying structure and properties of arithmetic operations (Chailkin & Lesgold, 1984; Collis, 1975; Kieran, 1989). In our research we have found that young children are capable of making such generalizations, constructing ways of representing them, and justifying them if

they are provided appropriate opportunity (Carpenter & Levi, 1999; Carpenter et al., 1999;). These findings are consistent with other recent studies (Bastable & Schifter, 1998; Davis, 1964; Kaput, 1999; Schifter, 1999; Tierney & Monk, 1998).

We have taken what we ourselves and others have learned about students' capabilities in algebraic thinking and developed a set of ideas about engaging teachers. Our work with teachers builds on the conception of teacher learning as a generative process interactively constituted in complex learning environments. We see that we cannot separate learning from the context in which it occurs and that we need to capture the evolutionary character of teacher learning. Our goal then is to provide teachers' opportunities to engage in inquiry about their students' mathematical thinking. What we have learned as we have used these ideas to work with teachers is that content plays a central role in what and how the teachers engage. The mathematical content plays into teachers' notions about their students and what they can accomplish as well as into their notions of mathematics.

We have found that it is not just the structure of the professional work that makes a difference but the interactions around those structures. (We have described the structures and processes elsewhere.) So while we can enumerate some key principals for supporting professional development (a) creating communities where the teachers are engaged in inquiry (b) student thinking provides a tool that engages teachers, makes explicit their and their students participation with the mathematics and provides a trace of the communities ideas, (c) understand the histories of cultures of the communities that we enter. What we did not realize was how these ideas interacted with the mathematical content on which the professional development is based. We have found that we may need to think differently about professional development for elementary school teachers around algebraic thinking.

We piloted our algebraic thinking work this past year in an urban elementary school. We wanted to use the work around algebraic thinking as a lever for changing teachers' mathematics practice and the ways they engaged with each other as a community. What we found was that the teachers at Lincoln could easily co-opt the algebraic thinking work to fit their notions of the teaching and learning of mathematics and the algebraic thinking work on the surface did not explicitly keep at the forefront a different way of thinking about the teaching and learning of mathematics.

We went into Lincoln Elementary anticipating the teachers would find the algebraic thinking "fit" with what they needed to focus on for their students. On the surface, the algebra looks much like what the teachers already do; the algebra work focuses on solving number sentences and understanding the relationships within and across mathematical expressions. It looks symbolic in nature. It involves problems that teachers see on the standardized test. It does not look like "fluffy" problem solving". We hypothesized that it would provide a reasonable entry point. What we did not anticipate was how the content of algebraic thinking we identified and the ways in

which that mathematics was made explicit fed into teachers existing notions in ways that did not help them think about how they might engage students in talking about their thinking or representing their ideas within the group. In our previous work the word problems did serve this purpose. We have found a number of ways in which the content plays out in the professional development differently than we would have anticipated. We need to think carefully about the mathematical content and its relation to teacher learning and professional development.

# **Discussion Groups**

## **THE MESSY WORK OF STUDYING PROFESSIONAL DEVELOPMENT: THE CONVERSATION CONTINUES**

Fran Arbaugh  
University of Missouri—  
Columbia  
arbaughe@missouri.edu

Catherine A. Brown  
Indiana University—  
Bloomington  
cathbrow@indiana.edu

Rebecca McGraw  
University of Arizona

At the 2001 National Council of Teachers of Mathematics (NCTM) Research Pre-session, the facilitators of this discussion group led a work session titled “Studying Professional Development is Messy Work: What are the Research Issues?” This PME-NA discussion group is designed to continue the conversation begun in 2001 and will focus on generating group goals for continued work. A second product of this discussion session will be group-generated research questions that will help guide future investigations of professional development for mathematics teachers. Participation in the 2001 Research Pre-session work session IS NOT a prerequisite of attendance at this discussion group.

As interest in study groups, lesson study, and other alternatives to traditional forms of professional development increases, the mathematics education community needs to have better descriptions of what these alternative forms of professional development entail and also what the effects on teachers are. But investigating these forms of professional development is often more complex than studying traditional forms such as workshops and courses (Zeichner, 1999). Researchers are frequently directly engaged as participants in the professional development activities; researcher-teacher relationships are sometimes intense and long-term; and some of the professional development activities themselves are hard to distinguish from the everyday work of teachers. All of this suggests a need to develop new ways to think about the characteristics of “good research” on professional development. Ultimately, designing “good research” on professional development will help us understand on a deeper level how teachers learn.

### **A Brief History of Prior Work**

At the 2001 NCTM Research Pre-session, the facilitators of this discussion group led a work session titled “Studying Professional Development is Messy Work. What are the Research Issues?” The description of this session read: “This work session will address research issues related to studying forms of professional development that involve intense, collaborative work by groups of teachers, teacher educators, and others.” Approximately 50 people attended the session. After a short presentation of research issues that have arisen in the facilitators’ research, participants were actively engaged in small work groups. They were given the following charge:

- Further refine the issues raised
- Raise additional issues
- Discuss ways to address the issues
- Record the 1 or 2 most interesting/pressing issues and proposed ways to address them
- Select a reporter to share these with other participants

After the small groups reported back to the whole group, we asked the question “Where do we go from here?” The following list contains the suggestions made by the group:

- Prepare a monograph in which research issues surrounding professional development are discussed.
- Sponsor a small conference that focuses on research on professional development.
- Begin a working group to set important variables and measurements for studying professional development, including measurements of “where teachers start.”
- Take up the issue of how to assess the impact of professional development on student learning.
- Develop ways talk about and link the research literature on teacher education, teaching, and student learning.
- Develop a framework, or frameworks, of the “bigger picture” of professional development, given that teachers “sit” within a culture.
- Design longitudinal framework(s) that allow for publishing/reporting out along the way.
- Think about new data collection sources.
- Think more deeply about the “phase out period,” that period of time when the grant money is ending and the researcher/professional developer begins to “phase out” involvement with the teachers.

The participants of the 2001 Research Presession Working Group brainstormed many important issues related to studying professional development, as indicated by the list above. It is now time to begin the work suggested by that group.

#### **Focus Issues for 2002 PME-NA Discussion Group**

Participants in this discussion group will focus on two issues that will support continued work of the group: 1) generating goals for the group; and 2) generating research questions regarding studying forms of professional development that involve intense, collaborative work by groups of teachers, teacher educators, and others. Each focus is expanded below.

## **Group Goals and Future Direction**

Given the list of “where do we go from here?” responses generated at the 2001 Research Presession, it is likely that the goals of this discussion group might include some items from that list (see previous section). As organizers of this session, we hope that this discussion group can become a PME-NA working group that collaborates to generate and share research on professional development. It is important that we use the time in this discussion group session to organize and prioritize future work for the group, work that begins by setting goals.

## **Generating Research Questions**

At an AERA session in April 2002, Deborah Ball challenged us to think about questions that should guide our work when studying professional development involving groups of teachers who work collaboratively to improve their practice. As a part of her challenge, she provided a set of questions that she feels are important for the community to consider. Those questions are reproduced here with her permission and include:

- How do teachers learn to collaborate?
- How do teachers learn to study their own and others’ teaching?
- What do we do after making teaching public to make it actually **VISIBLE** and **LEARNABLE**?
- How do we help teachers ask good questions about their practice?
- What does it mean to have rigor in research on practice?
- What does it mean to scrutinize or analyze practice?
- What is crucial about collaboration?
- What is the key element of collaboration?

Ball’s questions provide a “jumping off point” for this discussion group to generate a more comprehensive list regarding studying professional development involving groups of teachers collaborating to improve their practice.

## **Where Do We Go From Here?**

As we did at the end of the 2001 Research Presession Working Session, we will ask the question “Where do we go from here?” Based on the group goals generated earlier in the session, Arbaugh, Brown, and McGraw will take initial responsibility, under advisement of the group, for organizing participants for future work. 2002 PME-NA discussion group session notes and participant list will be compiled and distributed through email. If interest is strong, the facilitators of this discussion group are committed to organizing the group again for the 2003 PME-NA meeting.

## MATHEMATICS TEACHING ASSISTANT PREPARATION AND DEVELOPMENT

Timothy Gutmann  
University of New England  
gryphon@phrost.mv.com

Natasha Speer  
Michigan State University  
nmspeer@msu.edu

Teri J. Murphy  
University of Oklahoma  
tjmurphy@math.ou.edu

Teaching assistants (TAs) play a vital role in the mathematics education of undergraduates and may go on to become professors of mathematics. From the K-12 literature, we know that patterns of teaching practice, as well as beliefs about teaching and learning, form early in a teacher's careers. Yet, while there is a large body of research about K-12 teachers, researchers are only beginning to consider the development of TAs. To date, the small body of work that exists addresses TAs in two distinct ways: professional development, usually taking the form of week- or semester-long introductory programs to help TAs during their first teaching assignments; and research into the graduate student experience and the challenges TAs face, both in and out of the classroom. This discussion group will bring research- and practice-focused people together and provide a forum to begin identifying researchable questions and establishing agendas for future work. In addition, it will foster collaboration on these issues between K-12 and undergraduate mathematics educators.

### Introduction

At present, we know very little about the characteristics (including teaching practices, beliefs, challenges, needs, and understandings of mathematics and teaching) of graduate students who are mathematics teaching assistants (TAs) or about the factors that shape those characteristics. Over the past five years, mathematics educators have begun to address these issues in two ways: (1) by designing preparation and development programs that target mathematics graduate students who are or will be teaching undergraduates and (2) by beginning research programs focusing on the TA experience. As the community becomes more aware of the importance of TA development and of understanding the TA experience, there is a growing need to organize what has been done, to facilitate cooperative efforts at understanding these issues, and to discuss and determine needs for future work. In particular, in order that research and practice not be disjoint, it is critical that participants from multiple perspectives have opportunities to share their ideas, articulate challenges, report on progress, and establish further agendas for moving the field forward. To that end, this paper is meant to fuel a discussion by briefly describing each of the following related areas: the recent interest in undergraduate mathematics education that provides a context for research about TAs; the fundamental need and exciting opportunities for research about TAs; some of the research already in progress; and connections to TA preparation and development programs as well as to the K-12 literature. In the last section of this paper, we

present our expectations for the discussion group session at PME-NA XXIV in Athens, GA, and suggest potential research directions that the discussion group might pursue.

### **Undergraduate Mathematics Education**

Fueled by research and national reports about the state of the teaching and learning of college mathematics (National Science Foundation, 1986; Seymour & Hewitt, 1997), over the past two decades the amount of attention paid to undergraduate mathematics education has increased substantially. Efforts have been made to examine and to improve teaching and learning. These efforts have taken the form of instructional design projects (e.g., new textbooks, computer-based curricula), research on student learning, and (to a lesser extent) research on teaching at the undergraduate level. Although the focus of this paper is on research, the relative novelty of innovation in mathematics instruction at the college level is an important part of the context in which the research is conducted. Research in the teaching and learning of mathematics at pre-college levels (as well as some research on college teaching in general) has been ongoing since early in the 20<sup>th</sup> century, but research specifically in undergraduate mathematics education has only been active since the mid-1980's. These factors combine to make undergraduate mathematics education an arena flush with rich contexts for research.

Undergraduate mathematics education research is intimately related to research into mathematics teaching and learning at the pre-college level, but there are two important distinctions: the focus on questions surrounding undergraduate mathematics content and the individuals involved in conducting research in this area (Schoenfeld, 1994; Selden & Selden, 1993). First, undergraduate mathematics education research assumes students are enrolled in college courses, thus there tends to be a focus on student learning of mathematical topics typically presented in such courses, i.e., calculus, differential equations, linear algebra, and abstract algebra.

The second distinction is the different demographics of the researcher populations in each area. Pre-college mathematics education research is typically carried out by Ph.D. mathematics educators, and often involves some level of collaboration with teachers in schools. In some cases, researchers from the K-12 community have expanded their agendas to include examination of issues at the undergraduate level. Undergraduate mathematics education has also attracted the interest of many Ph.D. mathematicians, who have come to questions about student learning during their own teaching careers. Unlike their colleagues in mathematics education who are professionally interested in pre-college education, these mathematicians are most directly concerned with the success of undergraduate students in mathematics courses. Another way in which K-12 education researchers and mathematicians with an interest in education differ is that the latter group often begins with little formal exposure to the existing body of mathematics education research and learning theory. They succeed through a kind of on-the-job training and, thus, their experiences, competencies,

backgrounds, and perspectives are different from those of mathematics educators and are an important factor to consider. It is often these mathematicians who take responsibility for the design and implementation of TA preparation programs.

### **Need for Research about TAs**

At many universities, graduate student teaching assistants play a critical role in the education of undergraduates. TAs are often given significant responsibility for teaching lower-division courses, including courses for mathematics majors, service courses (e.g., engineering calculus), and content courses for prospective K-12 teachers. This responsibility comes in many forms: some TAs have sole responsibility for teaching a course, some teach recitation or discussion sections that accompany large lectures given by faculty, some work as homework graders, and some provide tutoring services to students. Whatever the form, contact with TAs can constitute a significant portion of undergraduates' instructional time in lower division courses. Thus, the potential influence that TAs have on undergraduate students' experiences with mathematics is tremendous.

In addition to their importance as TAs, the current pool of graduate students is also the source of mathematics faculty of the future. Several authors (e.g., Brown, 1985; Eisenhart, 1995; Lacey, 1977; Lortie, 1975; Zeichner & Tabachnick, 1985) have discussed the significance of early experiences in solidifying beliefs, developing practices, and setting patterns of social learning for new teachers. Thus, the time spent as a TA is the time during which young mathematicians will discover teaching in a way they will likely carry with them into their careers as faculty. A TA's first teaching experience provides rich opportunities to support and shape emerging instructional practices. Yet, traditionally, support structures and guided enculturation experiences have not been available, let alone an expected part of a graduate student's professional development. Although over the past two decades more attention has been directed at undergraduate education than was in the past, the focus of this attention has mostly been on areas other than instructional practices (e.g., curriculum development, uses of technology, assessment). These features of the context provide great challenges as well as interesting opportunities for research that has the potential to improve both current and future undergraduate mathematics education.

### **Connections to TA Preparation and Development Programs**

TAs often have a great deal of responsibility for instruction but little opportunity to learn how to teach in ways other than those they have experienced themselves or those modeled by their faculty mentors. Even for college and university faculty, early and ongoing instructional development opportunities tend to be somewhat limited. TAs (future faculty) will need a rich and reflective understanding of their teaching practices if they are to make informed decisions and respond professionally to changes in mathematics education. Yet, the preparation and support TAs typically receive is

minimal. Most arrive in graduate school with little or no prior teaching experience. Before they start to teach, they may attend a department- or campus-wide orientation session, lasting a few hours or a few days. The range of topics that are addressed in these sessions is broad. In a typical program, new TAs learn about campus, department and course policies and procedures. They may receive information about the specific course they are teaching and a list of tasks they are expected to perform (such as grading homework, administering quizzes, holding exam review sessions, etc.). They might also receive information about teaching, learning, and ways of interacting with students. In some cases, new TAs have the opportunity to practice teaching (often very briefly) and receive feedback (often very superficial) from their peers and/or people running the orientation sessions.

In efforts to provide ongoing development opportunities, some institutions run semester- or year-long seminars to introduce graduate students to their roles as teachers as they are beginning to function as TAs. In 1999 and 2000 the American Mathematical Society (AMS) - Mathematical Association of America (MAA) Joint Committee on Teaching Assistants and Part-Time Instructors sponsored Joint Meetings sessions about the preparation and development of mathematics graduate teaching assistants. At both of these sessions (designed for an audience of practitioners, not researchers), presenters described programs ranging from quick orientations to semester-long courses on teaching. Activities included reading about teaching and learning, microteaching, keeping journals, observing others teach, and participating in discussions (Murphy, et. al., 2000). Only a few presenters at these sessions referred to the literature on teacher preparation or professional development.

Additional ideas for curricula and reports of efforts were gathered in Case (1994). Rishel (2000) proposes mathematics-specific, basic strategies for new (and experienced) TAs to be successful. To fuel conversations about deeper issues related to undergraduate teaching, Friedberg, et al. (2001) offers crafted vignettes of common situations that challenge instructors' perspectives and behaviors. With support from the Fund for the Improvement of Postsecondary Education, these case studies were pilot-tested with groups of TAs over a period of years at a variety of institutions. Furthermore, recognizing that the mathematicians typically in charge of TA development programs lack experience with case study discussion as an instructional strategy, Friedberg, et al. held training workshops in the Boston area in 2000 and 2001 (see <http://www.bc.edu/casestudies> for more details). Despite the wealth of valuable ideas collected here, none of these resources was specifically based on research about teaching assistants or related issues.

More recently, Meel (2000) spoke at PME-NA XXII about using journaling and the reading of journals to help new TAs become reflective about their classroom experiences, as the beginnings of a project relating research and practice. The TAs who participated in Speer (2001) were teaching a particular kind of calculus discussion section for the first time and were simultaneously participating in a professional development

program for which Speer was partially responsible. These efforts to connect research and practice are impressive because, for the most part, researchers and TA educators have worked separately.

TAs themselves contribute significantly to college instruction and they may become faculty members with lifelong contributions to education, yet the historic lack of communication among players has led to a paucity of program models based on systematic investigations of TAs' contributions and challenges. TA educators have developed courses for beginning TAs to help address their first semester needs; they have published course materials; many have participated in orientation sessions at the start of the semester for incoming TAs. These projects are most frequently limited in scope and in publication to the department where the TA educator works. Rarely do TA development course projects lead to collaboration with members of the larger mathematics and mathematics education communities (Friedberg's (2001) contribution is a notable exception). Similarly, mathematics educators studying the experiences, beliefs, and contributions of TAs are distinctive in the field because of the relative isolation in which they have worked. While many are tangentially aware of the work of others, collaboration in the field has been rare. Communication has so far been limited, and there is a clear need for TA educators and for researchers to communicate, discuss, plan, and organize ideas, both within the groups and (perhaps more importantly) between the groups. The current climate is in part due to the emerging nature of the interest in the field, but its affect has been, thus far, to limit understanding and progress. The PME-NA discussion group was motivated primarily by a need for greater communication and opportunities for collaboration.

### **Connections to the K-12 Literature**

Literature addressing teaching and learning at the K-12 level includes a rich base of information about how preservice teachers think about mathematics and about the teaching and learning of mathematics. This base is extended to document how established teachers practice in and reflect upon their own classrooms. In particular, there is an emerging base of information about how teachers' beliefs and practices shape the implementation of reform. There is no comparable base of information about TAs, neither about their beliefs about mathematics, nor about the teaching or learning of mathematics, nor about how they understand and think about their own classroom practices. Indeed, although the research on general undergraduate mathematics teaching and learning is increasing, the body of literature that exists is still quite small relative to that at K-12 levels. Attention has yet to be focused on TAs specifically. One important gap is the lack of scientific documentation of what TA teaching typically looks like. Informed by efforts at the K-12 level, this basic research is needed to guide efforts to help TAs develop their teaching practices in productive ways.

K-12 teachers and TAs are different from and similar to one another in some interesting ways. Unlike most elementary and secondary schoolteachers, college

instructors do not typically participate in compulsory, extensive teacher preparation programs. Like elementary and secondary schoolteachers, TAs (and other college instructors) can become isolated from colleagues, with little or no opportunity to grow from interactions with other instructors (Lortie, 1975; Murphy, in press). For many, their first jobs as TAs will be the only time in their careers when they (may) participate in (essentially minimal) professional development about teaching. K-12 teachers, on the other hand, may encounter a variety of opportunities for professional development throughout their careers. Since faculty are unlikely to receive any further guidance regarding their teaching, the practices they develop as TAs may well shape their teaching for the rest of their careers. Support and professional development associated with their initial teaching may be the only formal opportunity to help college instructors develop their teaching practices in effective ways.

The similarities may point to ways in which the existing research base on K-12 teacher development can be applied to TAs. Differences may help identify areas where additional research is especially needed. In both situations, making use of and building on what is known from research in K-12 teacher development could be an important component of the design and implementation of professional development for TAs.

### **Research in Progress**

Thus far, most of the attention to TAs has been on professional development activities and programs. Now, however, the community is poised to engage in research in substantial ways and will be able to build on the momentum gained by research in undergraduate mathematics education and by the increasing investment in TAs as current and future key players in undergraduate education. Ideally, research directions will be based on the needs of TAs and TA educators and findings will inform the design of increasingly effective preparation and development programs.

Some groundwork research is already in progress. For example, DeFranco and McGivney-Burelle (2001) reported on TAs' beliefs about the nature of teaching and learning mathematics. Speer (2001) also conducted a study about TAs' perspectives, focusing on the instructional practices of TAs teaching calculus and the relationship between collections of beliefs and moment-to-moment teaching decisions in class. A broader approach is to consider the entire graduate experience. For example, Herzig (2001) investigated reasons for attrition among mathematics graduate students, finding a mismatch between the preferred work styles of students who left (e.g., collaborative) and the perceived culture of the discipline. Related work includes research that addresses the cultural climate in which mathematicians work. Examples of this approach are Gutmann's (2000) ethnographic case study of a small, teaching-focused mathematics department; Enzensberger's (1999) essay, which addressed the attitude toward mathematics common in the general population; and Damarin's (2000) sociological observation that mathematicians represent a marked category and, like other minority groups, operate in a world partially defined by their otherness.

The issue of enculturation is especially important. Graduate students somehow learn to function in their departments. To succeed, they need, or at least believe they need (Lacey, 1977), to adopt the habits and attitudes of their faculty mentors. Pressures to become part of the existing culture are strong. Even TAs who arrive in graduate school with substantial concern for undergraduate education and strong motivation to teach may find that holding on to those ideals is incompatible with success as defined by their department, their faculty mentors, and the discipline as a whole. With proper support and enculturation, it may be possible to build on and nurture good intentions and practices.

### **The Discussion Group at PME-NA XXIV and Potential Research Questions**

Inaugurated at PME-NA XXIV in Athens, Georgia, this discussion group is intended to generate ongoing conversation about potential research paths. The discussion group will facilitate dialogue among and between researchers and practitioners, at all levels K-16. Participants will be asked to speak for a few minutes to the group about their own interests and to summarize their connections to work with or about TAs. These introductions should assist group members in meeting potential colleagues and in beginning collaborative projects of mutual interest. Further time will be spent generating researchable questions and considering how best to organize the diverse contributions in the field for future productivity. As part of this process, we offered above an overview of some research-in-progress. We offer also the following sample of potential research questions that the discussion group might consider pursuing:

- (1) In what ways and to what extent does research about pre- and in-service teachers apply to TAs? In particular, what are the similarities and differences in knowledge and beliefs about teaching and about mathematics?
- (2) What are TAs' expectations about teaching? What are their self images in terms of thinking of themselves as teachers? How do these expectations/images evolve as TAs gain experience?
- (3) What are TAs' conceptions of mathematics? conceptions of teaching? conceptions of how students learn mathematics?
- (4) In terms of professional preparation and development, what can be transferred from the K-12 research? What adaptations need to be made for K-12 models to work in the TA setting?
- (5) What effects do students' perceptions of TAs have on them? What effects do faculty members' perceptions have on them?
- (6) What challenges/opportunities does cultural context present? How do TAs learn how to value teaching?
- (7) How are TAs similar to/different than K-12 pre-service/in-service teachers? As a result, how should the preparation and development of TAs be similar to/different than K-12 programs?

The community needs large-scale investigations to identify critical, widespread issues. Small case studies will provide in-depth understanding of TAs' perspectives and of the challenges they face. Research with longitudinal designs will inform the design of exemplary programs that have lasting impact on instructional practices. Given that TAs are critical agents in college instruction, such research is especially vital at this time of increased attention to the quality of education at the undergraduate level.

# **ACHIEVING EQUITY AND IMPROVING TEACHING IN MATHEMATICS EDUCATION THROUGH TEACHER EDUCATION AND PROFESSIONAL DEVELOPMENT**

Laurie E. Hart  
University of Georgia  
lhart@uga.edu

Martha Alleksaht-Snider  
University of Georgia  
marthaas@coe.uga.edu

This discussion group explores equity in mathematics education with an initial focus on integrating equity in mathematics teacher education and professional development. The group will analyze existing research regarding equity in mathematics education with the goal of identifying research findings important for P-12 teacher education and professional development. In addition, the group will make plans for further discussions at future PME-NA meetings. Four papers with a variety of perspectives on equity will serve as the starting point for the group's discussions. Laurie Hart and Martha Alleksaht-Snider will set the stage with a summary of recent research. Brian Lawler and Amy Hackenberg will explore the nature of equity and what it means to work for equity. Jae Hoon Lim will discuss implications for teacher education from a recent study of sixth grade girls' motivation for learning school mathematics. Vilma Mesa and Shari Saunders will describe a new secondary teacher preparation program with a social justice perspective for teachers in urban settings.

This discussion group explored equity in mathematics education with an initial focus on integrating equity in mathematics teacher education and professional development. This was the first meeting of the group. The discussion group analyzed existing research regarding equity in mathematics education with the goal of identifying research findings important for P-12 teacher education and professional development.

In the discussion group, four papers were presented with each discussing findings related to equity in mathematics education that are important for teacher education and professional development. Following these papers, the participants considered the following concerns: (a) how the research findings may be used in teacher education and professional development and (b) additional research findings about equity that extend the findings presented. Finally, participants generated ideas for future research that could inform teacher education and professional development. Organizers recorded the ideas generated in the discussion group and produced a summary to be distributed to the participants. Participants were invited to make plans for a follow-up discussion group at PME-NA 2003.

## **Overview**

Disparities in mathematics achievement and enrollment in higher level mathematics between White middle class males and other groups of students such as

females, African Americans, Latinos, Native Americans, and poor students have concerned educators at all levels for many years. Policy makers and researchers have acknowledged these differences in their calls for improving mathematics learning for all students. What has not been clear is how teachers, administrators, and counselors in individual schools and districts throughout the country might accomplish equity in mathematics with their students. Equally unclear has been how teacher educators and professional developers might support teachers, administrators, and counselors in understanding the barriers and supports to accomplishing high levels of mathematics learning for all students.

Our review of research conducted during the past decade suggests that important findings and perspectives related to achieving equity in mathematics education are available in the literature and need to be more accessible to teacher educators and professional developers (Alleksaht-Snider & Hart, 2001). Knowledgeable and committed teachers who have developed their own understanding of the ways in which racism, classism, and sexism affect mathematics teaching and learning are critical to equitable outcomes for students in mathematics (Alleksaht-Snider & Hart, 2001; Apple, 1992; Campbell & Silver, 1999; Love, 2001; Weissglass, 2000). Both beginning and experienced teachers need to develop capacity in mathematics education reform and skills for providing equitable instruction in order to support diverse students and their families in mathematics learning. Teachers require preservice preparation and professional development support in the areas of:

- mathematics education reform
- mathematics content for equity
- mathematics pedagogy
- identifying inequities and strategies to achieve equity in mathematics education
- building partnerships with families and communities.

Research discussed by Love (2001), Oakes and Franke (1999), and Weissglass (2000) has shown that beliefs that are pervasive in society can interfere with the attainment of equity in mathematics education. All those involved with and interested in the education of children may hold and convey many of these beliefs that can inhibit students' access to and attainment of high levels of learning in mathematics. In addition to beliefs, classroom processes and teaching practices are essential for understanding how schools and teachers contribute to differences in mathematics achievement by race, gender, and social class. Hart and Alleksaht-Snider (1996) have suggested that the concepts of resistance, engagement, and a sense of belongingness for underrepresented students in the mathematics classroom are important new ideas for mathematics educators to consider. Culturally relevant pedagogical strategies described by Gutstein, Lipman, Hernandez, and de los Reyes (1997), Ladson-Billings (1997), and Tate (1995) offer promise as a means for promoting engagement and a sense of

belongingness for poor students, students of color, and female students who are too often disengaged from mathematics.

The above provides a brief summary of some of the research that Hart and Allexsaht-Snider have identified as important for teacher educators and professional developers in mathematics education. The following sections provide summaries of three papers by mathematics education researchers from the United States, Asia, and Latin America.

### **EXPLORING THE ROOTS OF EQUITY IN TEACHER EDUCATION**

Brian R. Lawler  
University of Georgia  
blawler@coe.uga.edu

Amy J. Hackenberg  
University of Georgia  
ahackenb@coe.uga.edu

Characterizing equity as equal access to learning opportunities and resources (NCTM, 2000) is necessary but not sufficient when working towards an equitable mathematics education. We believe this characterization is insufficient because it may not adequately problematize how grouping happens. That is, it may take for granted common ways people identify other people (or themselves) and generalize them into groups, namely by race, class, and gender. We do not dispute that the phenomenon of grouping is necessary in order to operate in the world, or that race, class, and gender are powerful and pervasive ways that people group themselves or are grouped. What concerns us is that the phenomenon of grouping itself may often be ignored and that how we group requires deep examination (Secada, 1992) when considering the nature of equity and what it means to work for equity.

In order to reconstitute a definition of equity that takes into account rethinking how grouping happens, we believe we must begin with each person's responsibility to herself and others, what we will call "roots" of equity. While we cannot say categorically what is and isn't equitable in ways that transcend humans in particular contexts, we believe that the potential for realizing equity is heightened when the focus begins with these two roots. First, confidence and competence in one's own ideas and thinking are essential, coupled with an awareness of the fallibility and the perpetual incompleteness of these ways of knowing. This aspect of equity is related to Allexsaht-Snider and Hart's (2000) emphasis on belonging and engagement. Second, valuing others' confidence and competence in their knowing and regarding their knowing as not identical to one's own is necessary. We refer to this aspect as conferring an independent existence on others (Hackenberg & Lawler, 2002; Kamii & Housman, 2000). These roots of equity allow people to problematize how grouping happens because they open the way to forming judgments and generalizations about people founded

on qualities other than how one looks or where one lives (White, 2002). Furthermore, they acknowledge the tentativeness of all judgments and generalizations, thus contributing to efforts to rethink how we group.

This vision of equity for mathematics classrooms informs teacher education. Teachers need experiences that prepare them to examine and act upon these roots of equity. To accomplish this goal, the emphasis of teacher education should be to develop the ability to know learners. First, the teacher should develop her ability to listen hermeneutically (Davis, 1997) and construct models of students' ways and means of operating (Steffe & Tzur, 1994; Steffe & Wiegel, 1992). Eleanor Duckworth (1996) develops listening by instructing teachers to learn the thinking and reasoning of small groups of children. However, learning to listen is insufficient without developing an awareness of the nature of the constraints of one's socio-historical experiential reality. Thus, second, we believe mathematics teachers need to have experiences that allow them to know themselves, which involves having and investigating ideas about their environment, mathematics, and others. Julian Weissglass (1996) suggests techniques to know oneself that require intense, trusting relationships with colleagues. Learning to listen and to know oneself can then be practiced by the teacher and moreover, brought forth in learners.

We believe that when the teacher begins with learning the thinking of the student and growing aware of her own constraints, her classroom actions can become more equitable. By listening to students and constructing models of their thinking, the teacher develops cognitively informed and rich categories of students from which to operate. She values student's thinking and also enhances her competence and confidence in her own knowledge of students. This kind of teacher learning opens the way for making judgments and generalizations about students in ways that do not involve superficial or stereotypical aspects. Working toward awareness of the constraints of her own experiential reality opens the way for a teacher to continually rethink her judgments and generalizations. She develops her knowledge about the fallibility and incompleteness of all knowing, and at the same time can value students because her knowing about them is always subject to rethinking. We believe development of the roots of equity fosters a critical perspective at a personal level that has significant implications for a critical perspective on society and individuals' actions in society.

### **IMPACT OF ETHNICITY AND CLASS ON YOUNG ADOLESCENT GIRLS' MOTIVATION FOR LEARNING SCHOOL MATHEMATICS: IMPLICATIONS FOR MATHEMATICS TEACHER EDUCATION**

Jae Hoon Lim  
George Washington University

The relatively low achievement of female students in school mathematics has been of concern to many educators for the last few decades. Compared to male stu-

dents, female students report lower self-confidence in their abilities and performance in mathematics and, as a result, are more likely to avoid taking advanced math courses in high school (Eccles et al., 1983; Fennema & Sherman, 1978; Leder, 1992; Meece, Wigfield, & Eccles, 1990). Researchers suggest that various social and cultural factors may influence female students' experiences in learning mathematics and affect their motivation to acquire advanced mathematical knowledge (Reyes & Stanic, 1988).

However, a very few educational researchers have investigated the impact of various socio-cultural factors, particularly the combined impact of ethnicity and class, upon girls' mathematical learning experiences (Campbell, 1989). Few studies have explored how ethnicity and class influence girls' experiences with school mathematics and how girls understand and respond to the direct or indirect socio-cultural influences developing their motivation and academic identities in the mathematics domain.

This project was an ethnographic case study seeking to illuminate adolescent girls' experiences in learning school mathematics and to define the socio-cultural context of their motivation. In particular, this study examined the mixed impact of ethnicity and class upon their learning experiences and motivation. Case studies of five sixth-grade girls were conducted in a rural middle school in the Southeastern United States. Data analysis revealed a striking contrast between the perceptions of high-achieving girls and those of less well achieving girls. For the high achieving girls, the instrumental value of mathematics within the current educational system appeared to be the most profound reason for learning, as well as enjoying, school mathematics. These high-achieving girls successfully internalized school ideology while developing a positive academic identity, in contrast to others who were less well achieving.

In contrast, the majority of participating girls who were not fully persuaded by school ideology, including the instrumental value of mathematics learning, struggled more with various practices in their mathematics classrooms even though they continuously searched for the meaning of their learning and the feeling of "belongingness" in their mathematics classroom (Ames, 1992). In particular, minority students and those from lower socioeconomic backgrounds strove for meaningful mathematics learning in their classroom. They often posed more profound and critical questions about the meanings and values of school mathematics, expressing their desire for a deeper understanding of mathematical knowledge in the world. Yet, their questions were rarely answered or addressed in their mathematics classes, resulting in decreased motivation to learn school mathematics.

Various socio-cultural factors were found to influence each individual's experience with school mathematics. Among these factors are the mathematics streaming practices in their school and their socio-economic backgrounds, including the amount of parental support they receive for mathematics learning. Each participant also showed a variation in her ways of understanding and reacting to the inhospitable culture of mathematics classrooms, especially to female students.

Even though the above findings are based on a limited number of young adolescent girls and their teacher within a particular school setting, they provide teacher educators with insights into the complexity of issues of ethnicity and class, which have been minimally addressed in mathematics teacher education programs. First, the findings of this study pose a need for a critical discussion of various types of school-related ideologies, such as the instrumental value of learning school mathematics. While white middle-class society tends to accept these ideologies as given, ethnic minorities and working-class people are not fully persuaded by those concepts. The educational system in the United States has functioned against the hopes and interests of minority and working-class people, and this constitutes their experiences with and knowledge about schools (Spring, 1997). At the same time, it is important to understand that inculcating those school-related ideologies, such as the instrumental value of learning mathematics, in the hearts of minority girls and girls from working-class backgrounds is not the answer. Rather, educators have to accept their critical point of view as a stepping stone to developing a more meaningful way of learning school mathematics, one which is connected to students' everyday lives and ultimately leads them to become lifelong learners with the "continuing impulse to learn" (Oldfather & Dahl, 1994).

Second, it is important to note that some minority students, particularly high-achievers, experience a high level of anxiety and social pressure because they feel that their desires for school success and peer acceptance are contradictory to one another. This study illuminates the absurdity or ineffectiveness of fostering only "a few good students" out of many underachieving students with whom the few good students share their ethnic and cultural identities. What is most needed is not an individual teacher's isolated effort to "save" the few good students, but rather a collective, consistent, and self-reflective effort of the community of educators directed toward the entire group of minority and working-class students. Without such realization and commitment, it would be hard to make a significant difference, a positive long-term lasting effect, in the students' motivation and academic achievement in mathematics.

The third implication of this study is the need to help teachers recognize and counteract the classism historically plaguing our society and our schools. Because of the current economic disparity between whites and other ethnic minorities, classism is intertwined with racism itself. Some school practices and decision-making processes, such as mathematics streaming, often exacerbate the inequality in education by tending to prevent minority and working-class children from achieving a higher level of mathematical knowledge (Oakes, Gamoran, & Page, 1991). We need educators who eagerly and consciously monitor their school practices and raise their voices in resistance when their schools make a decision that may disadvantage girls, minority students, or students from working-class families. Ideally, a critical task of those who educate our educators would be to help pre-service and in-service teachers see themselves as advocates for girls, minority students, and students from working-class

backgrounds, and practice their every day “teaching as social activism” (Gutstein, Lipman, Hernandez, & de los Reyes, 1997, p. 732).

## **CRAFTING EXPERIENCES WITHIN A SOCIAL JUSTICE PERSPECTIVE FOR TEACHERS IN URBAN SETTINGS**

Vilma Mesa & Shari Saunders

University of Michigan, School of Education

Urban public schools in the United States today have special characteristics that make them unique. Diversity is one of the dimensions in which schools in urban areas differ from rural or sub-urban schools and, in consequence, the dilemmas that “urban” teachers face are quite particular and distinct from the dilemmas that other teachers face. For people involved in teacher preparation and development the most pressing question is what should be the nature of the experience that teachers interested in teaching in urban settings need to have in order to be able to (1) deal with diversity—especially given that the overwhelming majority of people entering the teaching force are still white, female, and not likely to have grown up very poor—and (2) persuade them that they can (i.e., give them legitimate, earned, grounded reasons to believe that they can) teach successfully in “urban” settings?

The Master of Arts with Secondary Certification program (MAC) at the University of Michigan is a very intensive field-based program for students seeking certification in secondary school teaching. The program seeks to integrate theory and practice and gives the students the opportunity to work with professionals on extensive field-based projects; the students are placed in urban public schools for the public school academic year. Shari Saunders has just begun coordinating one of the cohorts, whose students are placed in Detroit and surrounding areas. She is in charge of developing an urban education with a social justice orientation strand in the program. Together, we are developing a database of resources and activities that have been used in different subject matters (e.g., science, reading and language arts, mathematics) and that have been documented in the literature (Ayers, Hunt, & Quinn, 1998; Ayers, Klonsky, & Lyon, 2000; Calabrese-Barton, 1998; Calabrese-Barton & Osborne, 2001; Frankenstein, 1983, 1990; Gutstein, 2002; Howes, 1998) with the purpose of selecting those that would fit better in the program. Whereas we are interested in activities that deal with social justice issues, we are also interested in highlighting the connection with the content areas and in making sure that the activities help teachers realize that those activities can have an impact on students’ lives—that students can “write the world” (Freire & Macedo, 1987). Emerging from this work is a framework for selecting activities we think might be helpful in assisting other teacher educators in the process of designing an experience that will deal with other dimensions of diversity in urban school settings.

## FOSTERING THE MATHEMATICAL THINKING OF YOUNG CHILDREN, PRE-K-2

Robert P. Hunting  
East Carolina University  
huntingr@mail.ecu.edu

Constance K. Kamii  
University of Alabama – Birmingham  
ckamii@uab.edu

At root, mathematics is the science of relationships. The young child's world, like the teacher's/caregiver's, is a world of relationships. So mathematics is pregnant in every situation. It could be argued that teachers/caregivers are "teaching" mathematics, either consciously or unconsciously, in any social interaction with a child, whether they are aware of it or not. Experiences and vocabulary laid down in the early years will consolidate a huge fund of experience already begun before birth, and paves the way for fluent and accurate ways to communicate about relationships, as language arts, mathematics, science, and so on, are taught in K-12 programs.

There has been a renewal of interest in the mathematical capacities of young children following recent advances in cognitive science, convincing evidence that young children are more capable learners than current practices reflect, and evidence that good educational experiences in the preschool years can have a positive impact on school learning.

Evidence is also mounting that prior to formal schooling, children's potential for engaging in powerful and diverse mathematical behavior is not being recognized or realized by their teachers and caregivers (Ginsburg, Inoue, & Seo, 1999; Greenes, 1999). Balfanz (1999) noted that linkage of early childhood education—championed in the 19<sup>th</sup> century by Froebel and Montessori—with the public schools had the effect of suppressing child-centered curriculum. Since a kindergarten experience was not universal for all children, textbook authors assumed that young children started school with no prior mathematical knowledge or experience. Also public education shifted from a primarily rural system with flexible age-groupings to become dominated by the age-graded classroom of urban settings. Serious and sustained work in mathematics was delayed until the second or third grade. Thus an examination of representative mathematics material for preschoolers provides evidence for a minimalist curriculum—activities for teaching numbers to 10 and some basic geometric shapes.

It is important to differentiate the learning of connections between representations of mathematical symbols and representations of perceptual material such as patterns of items, sequences, and spatial phenomena, on one hand, and development of mental schema for dealing with mathematical relationships and problem solving, on the other. Both are important, so to emphasize one and neglect the other is wrong. One reason for the imbalance is that one is better understood than the other. Another reason is a commonly held view that basic skills should be taught before higher order thinking.

An example of the first might be learning to associate the symbol 5 with a collection of five items, or labeling with a symbol 5 the fifth item in a sequence. An example of the second might be mental coordinations allowing an understanding that a set of 5 items can be partitioned in various ways—one and four, two and three, three and two, four and one, two and two and one, and so on. It is this kind of knowledge which is the fuel for powerful problem solving. Piaget (1977) called it logico-mathematical knowledge; Skemp (1971) called it schematic learning.

Participants in this discussion group will be invited to contribute informal reports of recently completed research, research in progress, and/or assist in identifying problems and questions worthy of future investigation. Current and future collaborations between participants interested in common problems will be encouraged. Some areas that seem to offer fruitful avenues for investigation, together with some possible questions, include:

- I. Investigations of the nature of young children's mathematical thought and capabilities.
  - a. What emotional and affective factors influence young children's engagements in mathematical problem solving?
  - b. How powerful do affective factors appear to be in the early years?
  - c. How do verbal interactions between child and teacher/caregiver facilitate mathematics learning?
  - d. What strategies do young children use to solve particular mathematical problems?
  - e. What are the foundations of young children's reasoning in core areas such as probability, combinatorics, multiplicative thinking, part-whole relations, spatial relations, and so on
  - f. What is the relation between logico-mathematical development and "school" mathematics? How can one serve the other?
  - g. What are the mathematical features of children's play? Are some play activities more likely to provoke mathematical reasoning than others?
- II. Investigations of the role of teachers/caregivers in fostering mathematical thought.
  - a. What do teachers/caregivers of young children know about mathematics? What is their background, particularly with respect to providing mathematical experiences for young children?
  - b. What do teachers/caregivers of young children believe about mathematics, particularly the mathematics that is appropriate for young children?
  - c. How do teachers/caregivers interact with young children during a mathematical learning activity? What interactions are conducive to learning?

- d. What kinds of support materials and other assistance do teachers/caregivers need to bring forth mathematical growth in young children?
  - e. What sorts of interventions (e.g., workshops, courses) are needed to assist teachers/caregivers provide meaningful mathematical experiences for young children?
- III. Investigations of what mathematics young children can learn using computer-accessible materials.
- a. Can young children learn mathematics using computer-accessible materials? What is the role of the adult in computer-situated mathematical problem situations?
  - b. What role can computer technology play in the mathematical development of young children?
  - c. Can young children's ability to learn mathematics using computer-accessible materials be enhanced by exposure to conventional materials first?
  - d. Is there evidence of transfer from knowledge gained from computer-accessible materials to problems set in non-computer-based environments?
  - e. Are some kinds of games more efficacious for enabling transfer to other problem contexts? If so, what are their features?
- IV. Investigations into the nature and role of mathematics curriculum and professional development.
- a. What early childhood mathematics programs work, and what are their characteristics?
  - b. What insights, theories, and practices from primary mathematics education are transferable to the preschool situation?
  - c. How can mathematical thinking be fostered through music, story books, outside activities, movement, etc?
  - d. Are there cultural or social class differences in the ways young children engage in mathematical experiences? If so, how can early childhood teachers and authors of mathematics curricula take account of such differences?

## **AN INTEGRATED APPROACH TO THE PROCEDURAL/ CONCEPTUAL DEBATE**

Bethany Rittle-Johnson  
Carnegie Mellon University

William Baker  
Hostos Community College  
wbaker@hostos.cuny.edu

This discussion group will be pursuing the clarification of the relationship between the conceptual and procedural aspects of mathematical knowledge. The organizers propose an important shift of focus in the debate, from the question of developmental primacy of one aspect over the other to the question of an integrated development of both.

The organizers of the discussion group represent two distinct approaches to mathematics education, that of “pure” research and that of teaching-research. Dr. Mindy Kalchman and Dr. Bethany Rittle-Johnson are new young researchers in Mathematics Education and Educational Developmental Cognitive Psychology. Kalchman’s interest in procedural/conceptual knowledge developed out of work on micro-genetically analyzing sixth grade students’ progression from a procedural to an object (or reified) understanding of basic functions. The procedure and concept involved in this process seemed inextricably linked in ways worth investigating. Rittle-Johnson’s interests in procedural/conceptual knowledge developed as a result of theoretical efforts to understand mechanisms of cognitive development..

On the other hand, Dr. Baker and Dr. Czarnocha are teacher-researchers from a community college in New York City, whose interest in the subject is motivated by their students’ problematic performance in Remedial and Developmental Mathematics courses in the bilingual, Spanish/English context. Equally important in this motivation is the public evidence of serious classroom misunderstandings concerning the instruction along the procedural/conceptual divide in public schools. [See appendix.]

The majority of past research and theory on these relations has focused on whether conceptual or procedural knowledge emerges first (e.g., Rittle-Johnson & Siegler, 1998; Hapaasalo & Kadijevich 2000). The developmental precedence of one type of knowledge over another has been hotly debated and fueled by contradictory results (e.g., Gelman & Williams, 1998; Siegler, 1991; Siegler & Crowley, 1994; Sophian, 1997). This debate over which type of knowledge develops first tends to obscure the gradual development of each type of knowledge and the interactions between them during development. Rather, we propose an alternative view in which we posit that

throughout development, conceptual and procedural knowledge influence one another in mutually supportive and integrated ways. This view allows for the simultaneous and intertwined instruction of both conceptual understanding and computational fluency called for recently by (Kilpatrick, Swafford & Findell, 2001).

The purpose of this discussion group is to bring together researchers, teacher-researchers and mathematicians to move beyond the debates on “which come first” and “which is more important” to focus on the bi-directional relations and inner structure within the integrated conceptual/procedural mode of knowledge. We see the discussion as the beginning of a longer interdisciplinary process involving cognitive and developmental psychologists, education professionals, mathematicians and teacher-researchers to formulate a comprehensive research/instruction program to deal effectively with the procedural/conceptual divide across the full spectrum of K-16 curriculum. In terms of a longer terms strategy, we are aiming for the publication of a volume articles which will expand and develop issues signaled in the important Hiebert book (Hiebert, 1986) while focusing on the integrated approach to p/c issues. The development of themes and research questions to be discussed in the volume will be the primary way in which the attendees of the discussion will be pulled into active participation. The creation of the collaborative research teams addressing the research issues formulated during the discussion, is one of the ways through which the discussion group intends to transform itself into a Working Group or Research Forum at the next joint PME/PME-NA meeting in Hawaii. If this dream actualizes, we envision the collaborative teams working together throughout the intervening year, possibly aided by a small grant.

### **The Program of Work at the Meeting**

The sessions will have four parts. First, we will provide a sketch of the historical development of the procedural/conceptual issue drawn from the integrated point of view. Second, we will discuss the language of elementary algebra where procedural and conceptual aspects are correlated yet independent variables in promoting academic growth. Here, “independent” signifies that neither can be derived from the other one; they are irreducible (Baker & Czarnocha, 2002). Then, we will present two models of procedural/conceptual integration. In the iterative model, Rittle-Johnson proposes that conceptual and procedural knowledge develop iteratively, with increases in one type of knowledge leading to increases in the other type of knowledge, which trigger new increases in the first (Rittle-Johnson, Siegler & Alibali, 2001). In the coordinated model, Kalchman suggests that conceptual and procedural knowledge are co-active elements in the development of students’ more general numeric and spatial understandings of any domain in mathematics.

### Summaries of Presentations

#### **Degrees of Independent Activation of Procedural and Conceptual Modes of Acquiring Knowledge- The Case of Algebra**

This study of the relationship between written mathematics and procedural problem solving knowledge grew out of the need to address pedagogical needs of bilingual, Spanish/English students of an urban community college. The focus on the mutual positive influence of the conceptual and procedural modes of thinking, translated in this context into two research questions: (1) to what degree one can positively influence learning of language through the learning of mathematics (Czarnocha & Prabhu, 2000), and connected one, (2) to what degree one can positively influence the mastery of mathematical procedures with the proper use of written mathematical language. The answer to these two questions depends, naturally, on the degree to which these procedural and conceptual modes of mathematical thinking can be independently activated during an instruction cycle. This is the main focus of this study. Of separate interest is to observe that the answer to this basic question is also a definite statement in the context of Piaget/Vygotsky debate (Baker & Czarnocha, 2002).

In order to employ writing as a tool to both measure and promote conceptual development we coordinate the three-step model due to Sfard (1991, 1992, & 1994), which is based upon the work of Piaget with the theoretical framework of (Shepard, 1993) who matches levels of conceptual development with the appropriate writing categories due to Britton (Britton et al., 1975). In the model of Sfard, concepts are assimilated into the schema in the last stage of a three-step abstraction process.

“A constant three step pattern can be identified in the successive transitions from operational to structural conceptions: first there must be a process performed on the already familiar objects, then the idea of turning this process into a more compact, self contained whole should emerge, and finally an ability to view this new entity as a permanent object in its own right must be acquired. These three steps will be called interiorization, condensation and reification.” (Sfard, 1992, pp. 64-65)

*Interiorization.* According to Sfard, a procedure is interiorized when it, “can be carried out through mental representations, and in order to be considered, analyzed and compared it needs no longer to be actually performed.” We match the interiorization step, with the late initial learning phase and generalized narrative writing category in Shepard’s work. In this phase Shepard recommends writings that produce, “personal examples of concepts” or that explain, “definitions of procedures in one’s own words.” In this phase we continually asked our students to translate algebraic expressions and expressions back and forth between language and symbolic language.

*Condensation.* According to Sfard, “at this stage a person becomes more and more capable of thinking about a given process as a whole without feeling an

urge to go into details.” In describing condensation, Sfard makes an analogy to computer algorithms when she writes that condensation allows the individual to look at a procedure as autonomous, “from now on the learner would refer to the process in terms of input-output relationships rather than by indicating any operations.” On the effect that condensation has on an individual’s ability for abstraction she writes, “Thanks to condensation, combining the process with other processes, making comparisons, and generalizations become much easier.”

We match the condensation step of Sfard with the intermediate learning phase and the low-level-analogic and analogic writing categories in Shepard. In this phase Shepard suggests, “explaining how to solve a problem” and further, “explaining how concepts are related,” or explaining why, “concepts and procedures either do or do not apply.” Thus, at this phase students’ were required to turn their meta-cognitive reflection away from the definitions or rules of the procedures and towards the conditions that govern their use, as well as the difference and similarities between procedures or conceptual objects.

*Reification.* In the words of Sfard (Sfard, 1992), “the condensation phase lasts as long as a new entity is tightly connected to a certain process.” Of reification she notes, “the new entity is soon detached from the process which produced it and begins to draw its meaning from the fact of its being a member of a certain category.” In Sfard’s model of conceptual development, like all models based upon Piaget’s work conceptual development takes place in the framework of a cognitive schema. Thus, the last step of reification is identified with structuring and organization of one’s cognitive schema, a step necessary for conceptual development. As explained by Sfard, for an individual who has not organized their schema, “information can only be stored in an unstructured sequential cognitive schemata.” In contrast for an individual with a structural understanding, their cognitive schemata has a “compact whole” thus through a process of ordering or restructuring, it becomes a “hierarchical schema.” Furthermore without such an ordering, “there is hardly the place for what is usually called meaningful” (Sfard, 1992).

We match the reification step of Sfard with the early terminal phase and the analogic-tautologic writing category used in Shepard, who recommends writing categories that involve, “speculating about several different ways to solve a novel problem.” More specifically in our work we required students to focus their meta-cognitive reflection not on the procedures and not on the rules that govern their use but instead on the strategies involved when applying procedural knowledge in problem solving. Our objective was to encourage students’ organization and structuring of their cognitive schema.

## Results

For slightly over 180 students ( $n = 183$ ) the correlation between course average and GPA was  $R = 0.398$ , which was significant at the 0.01 level (high degree of significance). The corresponding  $R$ -square value was 0.158 and thus approximately 15.8% of the GPA was determined by course average. The correlation between writing scores and GPA was 0.402, which was also significant at the 0.01 level. When we used both course average and writing scores as independent variables together to explain GPA, the  $R$ -value was 0.455 and the corresponding  $R$ -square value was 0.207. Thus, approximately 20.7% of the GPA was explained using course average and writing scores. This represents an increase of 37% over the 15.8% explained using only course average. It is not to be expected that course average and writing scores in one class would explain most of a student's GPA throughout their college career. However, the 37% increase explained GPA when writing scores were added to course average is an indication of the important role written mathematical thought has in learning and cognitive development. The  $F$ -value of this multivariate model was 23.952, which had a 0.000 significance rating, thus the use of writing scores and course average resulted in a very significant model in which neither course average nor writing scores dominated the other. In particular, writing scores were not dependent upon the ability to apply one's procedural knowledge.

## Analysis

We have argued that written mathematical thought by its reflective nature is predominately composed of conceptual thought and meta-cognitive reflection upon procedural knowledge, both of which characterize the more advanced stages of development in Sfard's model. In contrast, we have argued that computational proficiency is predominately composed of the ability to apply procedural knowledge, which epitomizes the initial stage of development. Our result that, written meta-cognitive reflection and conceptual thought are independent of an individual's ability to apply his or her procedural knowledge provides evidence against Piaget's position interpreted as the "genetic view" (i.e., the more advanced stages of cognitive development are dependent upon completion of the first "interiorization" stage).

This result indicates that reflection upon procedural knowledge is not always a by-product of the repeated actions that characterize the "interiorization" stage. Instead, *meta-cognitive reflection can proceed during the act of writing about mathematics as well as through the process of repeated actions*. Moreover, this result provides evidence in support of Vygotsky's position that development can proceed through reflection, while writing, upon existing conceptual knowledge independently of the "interiorization" process (i.e., reflection due to repeated actions).

### **Iterative Model**

Rittle-Johnson proposes that conceptual and procedural knowledge develop iteratively, with increases in one type of knowledge leading to increases in the other type of knowledge, which trigger new increases in the first (Rittle-Johnson, Siegler, & Alibali, 2001). For example, limited understanding of some domain concepts could guide students' attention to important problem features and facilitates generation and use of a correct procedure. In turn, developing this procedural knowledge could lead to improvements in conceptual understanding, perhaps by freeing cognitive resources for noticing patterns and relations, highlighting the importance of certain problem features, or revealing certain misconceptions. Improvement in problem representation is one particularly promising mechanism underlying these iterative relations.

Evidence from 4 studies on children's learning about the equal sign and about decimal fractions support this iterative model for the development of conceptual and procedural knowledge. These studies raise important new questions for curriculum design about the timing and sequencing of instruction on concepts and procedures.

#### **Study 1**

The goal of Study 1 was to provide causal evidence for the bi-directional relations between conceptual and procedural knowledge. Students received instruction on a concept or a procedure, and we assessed the impact of instruction on knowledge of the other type (Rittle-Johnson & Alibali, 1999). The domain was mathematical equivalence, or the idea that quantities on both sides of an equation are equal. The target problems were equivalence problems such as  $3 + 4 + 5 = 3 + \underline{\hspace{1cm}}$ .

Participants were 59 fourth and fifth graders who solved equivalence problems incorrectly. Students completed assessments of conceptual knowledge (e.g., What does the equal sign mean?) and procedural knowledge (e.g.,  $7 + 4 + 8 = 7 + \underline{\hspace{1cm}}$  and  $3 + 6 + 2 = \underline{\hspace{1cm}} + 2$ ) before and after a brief intervention. For the intervention, students were randomly assigned to receive conceptual instruction, procedural instruction or no instruction on equivalence problems in an individual session.

Students in both the conceptual and procedural instruction groups showed greater gains in conceptual understanding and use of a correct procedure than the control group. The conceptual instruction group was better able to adapt a correct procedure to solve transfer problems. Overall, these findings indicate that improvements in conceptual knowledge can lead to improvements in procedural knowledge and that improvements in procedural knowledge can lead to improvements in conceptual knowledge.

#### **Study 2**

The goal of Study 2 was to use individual differences in prior knowledge and learning to assess the iterative relations between conceptual and procedural knowledge and whether problem representation is a link from conceptual knowledge to improved procedural knowledge (Rittle-Johnson, Siegler & Alibali, 2001). The

domain was decimals, with a focus on decimal magnitudes. The target problems were placing decimals on number lines.

Participants were 74 fifth graders. The intervention was a computer game the author designed called "Catch the Monster." To catch the monster, students needed to choose the correct location for a given decimal on the number line or to choose the decimal that corresponded with a given location on the number line. Before and after participating in the individual intervention session, students completed assessments of conceptual knowledge (e.g., What numbers are worth the same amount as 0.6?) and procedural knowledge (e.g., Place 0.54 on the number line).

Students began the study with some prior conceptual knowledge of decimals. Students' prior conceptual knowledge predicted improvements in their procedural knowledge. In turn, these improvements in procedural knowledge predicted improvements in students' conceptual knowledge. To understand the link from conceptual knowledge to improved procedural knowledge, we coded students' explanations of the answers to the intervention problems for whether students represented each problem correctly (e.g., noted the value of the digit in the tenths). As expected, prior conceptual knowledge predicted frequency of correct problem representation during the intervention, and correct problem representation predicted improvements in procedural knowledge. Overall, these results support the iterative model and suggest that improved problem representation may be one mechanism in the model.

### **Study 3**

The goal of Study 3 was to manipulate problem representation and examine the causal influence on improved procedural knowledge (Rittle-Johnson, Siegler, & Alibali, 2001). The intervention, assessments and design were the same as in Study 2 with minor modifications. Two manipulations of problem representation were used during the intervention: 1) Prompts to notice the first digit after the decimal point, along with highlighting this digit in red, and 2) marking the tenths on the number line. Participants were 117 fifth and sixth graders. Students were randomly assigned to one of four conditions based on the 2 by 2 crossing of the manipulations.

Both manipulations helped students to represent more problems correctly during the intervention. Both manipulations also led students to make greater gains in procedural knowledge, although it was only the combination of the two manipulations that led to sustained gains in procedural knowledge. These results indicate that improved problem representation leads to improved procedural knowledge and suggests that problem representation is an important mechanism within the iterative model.

### **Study 4**

The goal of Study 4 was to evaluate the instruction implications of the iterative model. We compared learning from iterative instruction, where conceptual and procedural lessons were interleaved, to concepts-first instruction, where all the conceptual

lessons were presented before the procedural lessons (Rittle-Johnson & Koedinger, this volume). The domain was decimal fractions, focusing on concepts of place value and re-grouping and procedures for adding and subtracting decimals.

The intervention was part of a sixth-grade curriculum we are designing that incorporates a computer-based intelligent tutoring system. This study focuses on a manipulation within the tutoring system where we varied the order of 3 conceptual lessons and 3 procedural lessons. In the conceptual lessons, students were asked to enter a decimal number in a place value chart and then to show the value of the number in novel ways using regrouping. In the procedural lesson, students were given word problems that required adding or subtracting two decimal numbers. The order of these lessons varied by condition. In the *concepts-first* condition, all three conceptual lessons were presented, followed by the three procedural lessons. In the *iterative* condition, the first conceptual lesson was presented, followed by the first procedural lesson, followed by the second conceptual lesson, and so forth. Participants were 72 sixth graders.

Students in the iterative condition made greater gains in procedural knowledge, and comparable gains in conceptual knowledge, compared to the concepts-first condition. In particular, students in the iterative condition were less likely to make digit alignment errors when adding and subtracting decimals (e.g.,  $8.41 + 25 = 8.67$ ). Introducing the procedural task early, and interleaving it with conceptual instruction, seemed to help link and strengthen knowledge shared by the conceptual task and the procedural task.

### **Open questions**

This research supporting an iterative model for the development of conceptual and procedural knowledge raises many new questions about the timing and sequencing of instruction on concepts and procedures: What is the optimal time-scale for interleaving instruction on concepts and procedures – minutes, hours, days, weeks, months? What is the smallest change in one that produces noticeable change in the other? Why does improvement in one type of knowledge sometimes not lead to improvements in the other and how can instruction help to avoid this? When can conceptual and procedural knowledge not be separated? Audience discussion of these issues will be invited.

### **The Coordinated Model**

In this presentation, Kalchman will focus on the design and implementation of mathematics curriculum that attends to the simultaneous development of procedural and conceptual knowledge in a domain of learning. Her presentation will have four parts. First, she will present a grounding theoretical framework that guides the development of curriculum for her research. Second, she will present a curriculum for the teaching and learning and mathematical functions that facilitates the development of procedural and conceptual knowledge for students from middle school through to

secondary school. Third, she will present empirical evidence of students using both conceptual and procedural knowledge as a result of engaging in the experimental curriculum. These studies involved students from Grades 6 through 11. And fourth, she will open up discussion about designing curriculum, which simultaneously develops conceptual and procedural knowledge in a domain of mathematical learning.

### **Theoretical framework**

At the 2001 PME-NA meeting in Snowbird, Kalchman and Fuson presented a paper in which they attempted to apply issues of conceptual and procedural development to Case's theory of central conceptual structures as it relates to children's learning of mathematical functions (Kalchman & Fuson, 2001). Very generally, in Case's theory (Case, 1992, 1996), children develop understanding in any domain of learning by progressing through a four-stage sequence of elaborations and integrations of two primary mental schemas. One of these schemas is primarily numeric for mathematics and the other is primarily spatial. When these schemas are sufficiently elaborated and then integrated, a new psychological unit, which he called a central conceptual structure (CCS) is formed.

In Kalchman and Fuson (2001), they suggested that within each of the primary numeric and spatial schemas, conceptual and procedural knowledge were being co-developed at each stage of elaboration and integration. That is, there is initial and distinct conceptual and procedural numeric understandings as well as initial and distinct conceptual and procedural spatial understandings. When the initially separate numeric and spatial schemas integrate, so does the conceptual and procedural knowledge previously connected only to one particular schema. Thus, the resulting CCS is an intricate weaving of conceptual and procedural knowledge within a larger framework of a child's newly integrated understanding of, in this case, functions.

Although the relationship of a CCS to the ongoing and simultaneous development of conceptual and procedural knowledge in a domain of mathematics was begun for the 2001 meeting, there are still many issues that need to be further explored. For example, what is the difference between the "small-c" conceptual understandings that are considered within each of the primary schemas and the "big-c" Conceptual understanding of a domain that is achieved upon the formation of a central conceptual structure?

### **The curriculum**

The functions curriculum referred to earlier was designed in the traditions of Case's theory of cognitive development. Essentially, that means that curriculum was designed for the express purpose of first elaborating students primary numeric and spatial understandings of functions and then integrating them. Empirical studies of students' learning with this curriculum have consistently and repeatedly shown through task analyses that such elaborations and integrations occur following instruc-

tion. The question, which was asked of me, and which I continue to pursue, is: Which parts of the curriculum develop and elaborate the primary numeric versus the spatial schemas in general? And furthermore, which parts of the curriculum develop conceptual numeric versus procedural numeric knowledge and which parts develop conceptual spatial versus procedural spatial knowledge?

### **Empirical results**

Empirical results come from pre and posttest responses to a functions test developed by Kalchman and Case (see Kalchman, 2001). Classes of students in Grades 6 through 12 participated in the treatment-comparison studies. The purpose in sharing these results is not so much to “present” results as to work with the participants of the discussion groups to understand the proportion of conceptual and procedural indicators in students’ responses to individual items. Responses in general will be examined as well as the differences between responses from students who learned functions with the experimental curriculum and those who learned with a modern textbook approach.

### **Discussion**

Questions driving this open discussion include: ways of improving current curriculum (including the functions curriculum) to improve students procedural fluency and conceptual organization in a range of domains; participants ideas and opinions on this model of ongoing co-development of procedural and conceptual knowledge both within each of the primary numeric and spatial schemas associated with Case’s theory of intellectual development and within the integrated central conceptual structure; differences between “small-c” and “big-c” conceptual understanding in a mathematical domain.

### **Initial Observations**

The inter-domain comparative analysis implicit in the organization of this discussion group suggest some interesting observations. First, the results of Rittle-Johnson and Kalchman seem to represent two conceptually independent solutions to the same problem of finding the dynamics for the integrated procedural/conceptual development, each coming from a different research paradigm: the strategy - choice approach and the schema development (Baroody, 2001; Geary, 1994). The presence of theses two solutions, while providing the answers to the original question: What is the integrative relationship between the two modes of mathematical thinking, creates, of course, a new question: What is the relationship between these answers, between the strategy - choice approach and schema development approach and how does it manifest itself in instruction and learning?

Second, there is an interesting division in the meaning of the “conceptual” along the K-12 curriculum. While it seems that arithmetic as well as pre-calculus and calcu-

lus research utilize numerical/visual relationship to express the procedural/conceptual character of the domain, algebra procedural/conceptual research has utilized numerical/verbal relationship (algebra has been seen here as generalization of arithmetic). Does this difference reflect the inherent difference between mathematical domains or the difference in the developmental progression of students, or both? Would the composition of numerical, visual and verbal modes of thinking be useful from the instructional point of view? How would it affect the procedural/conceptual integration?

The expression of the procedural/conceptual duality through procedural/language interaction brings one closer to Vygotsky's duality between thought and language (Vygotsky, 1986), where the fundamental unit of analysis, which motivated the thrust of his thinking, was the "verbal thought". What could be the corresponding unit of analysis for the numerical/spatial manifestation of the procedural/conceptual divide and its integration?

### Appendix

*New York Post*, Tuesday, April 17, 2001

This inset appeared in the New York Post article as an example of the reform motivated instruction and was provided by a disgruntled parent from a public school in Brooklyn.

**5th-Grade math: Go figure**

This example was provided by a disgruntled parent, whose fifth-grader is being taught "New Math" in a Brooklyn public school.

| Traditional  | THE "NEW" MATH  |   |  |
|--|---|---|--|
| $\begin{array}{r} 14 \\ \times 9 \\ \hline 126 \end{array}$ <p>Multiply 9 by 4, which equals 36. Put down the 6, and carry the 3 to the next column. 9 times 1 equals 9, plus 3 equals 12. Put down the 12. The answer is 126.</p> | <p><b>A Start with <math>10 \times 9</math></b></p> $\begin{array}{r} 10 \times 9 = 90 \\ 4 \times 9 = 36 \\ \hline 90 \\ + 36 \\ \hline 126 \end{array}$ <p>First multiply 10 times 9, which equals 90. Then multiply 4 times 9, which equals 36. Then add 90 to 36, which is 126.</p> | <p><b>B Start with <math>7 \times 9</math></b></p> $7 \times 9 = 63$ <p>then 14 is double 7, so double 63 is</p> $126$ <p>Multiply 7 times 9, which equals 63. 7 is half of 14. Since 14 is twice 7, multiply 63 times 2, which is 126.</p> | <p><b>C Start with <math>14 \times 10</math></b></p> $14 \times 10 = 140$ $140 - 14 = 126$ <p>Multiply 14 times 10, which equals 140. Instead of 14 times 9, therefore, that answer is 14 more than it should be. Then subtract 14 from 140, and come up with 126.</p> <p>In each case, the students break down the problem into smaller ones to come up with their answers.</p> |

From the cognitive point of view (as distinct from the political one), it takes some time to realize what could possibly be the reason for that feeling on the part of a parent, especially since computationally everything seems OK. A closer look, however, and taken especially from the point of view of the procedural-conceptual dichotomy, gives a lot of food for thought. It becomes clear why all three "New Math" columns A, B and C might be quite confusing in this presentation as opposed to the traditional vertical multiplication based on the positional notation. For example,

in the column A, the presentation starts from  $10 \times 9 = 90$   
 $4 \times 9 = 36$  . To an inexperienced

mind, an immediate question comes to mind, as to where 10 and 4 came from. Before, there were two digits 1 and 4 in one number 14 being multiplied by 9 while now there are two numbers 10 and 4. In other words, there is an important step missing, the step which explicitly shows the interaction between the positional notation and the use of the distributive law  $14 \times 9 = (10 + 4) \times 9 = 10 \times 9 + 4 \times 9$  . Without this step the whole procedure outlined in this column is intuitively rather weak. The standard manner of multiplying is able to bypass that point by virtue of the role of positional notation and visual/spatial organization partaking in the vertical method of multiplying numbers. A similar problem appears in column C (distributive law) and in column B (associative law). Looking together at columns A, B and C, the pedagogical problem in the design of the technique becomes clear. In these columns only the procedural aspect of the techniques was utilized, while, in fact, both conceptual and procedural aspects are needed. Moreover, since the whole instruction here seemed to be geared towards showing the conceptual richness of multiplication process, it seriously missed it by focusing purely on its procedural aspect. Clearly, the understanding and the coordination of the relationship between the two aspects of knowledge in this particular mathematical situation was missing in the presented instruction and, quite possibly, contributed to the confusion. This little analysis underlines the urgency with which the research community centered around the reform in mathematics education needs to attend to the integration of the p/c divide and, through the coordination of research with teaching, introduce it into instruction.

## **INVESTIGATING PRESERVICE ELEMENTARY TEACHERS' ATTITUDES AND BELIEFS TOWARD MATHEMATICS**

Julie Sliva  
San Jose State University  
Sliva@math.sjsu.edu

Cheryl Roddick  
San Jose State University  
Roddick@math.sjsu.edu

This paper explores research completed on preservice teachers' attitudes toward mathematics. Our findings suggest that after implementing curricular changes in the areas of cooperative learning, writing, technology, and increased usage of hands-on teaching methods, we were able to positively impact preservice teachers' attitudes. In addition, this paper is an investigation /discussion into best practices in conducting research on preservice teacher attitude.

As mathematics educators preparing students to teach mathematics, we have often thought that the beliefs, attitudes and experiences our students have had learning mathematics may have an impact on their learning and performance in mathematics, which ultimately may affect how they teach mathematics. Beliefs that students hold about mathematics and their abilities to perform mathematically are critical in the development of their responses in mathematical situations. This discussion group provides a forum to share best practices in conducting research on attitudes and beliefs.

Affective variables related to the learning of mathematics play an important role in the development of preservice teachers. Throughout the process of learning mathematics, preservice teachers collect a wide range of experiences. Both positive and negative, these experiences have led to the development of their beliefs and attitudes about mathematics. Recent research has found that teachers' beliefs about mathematics and the teaching of mathematics are significantly influenced by their mathematical experiences as a student (Brown & Borko, 1992; Brown, Cooney & Jones, 1990; Raymond, 1997). Furthermore, research has found that success in solving mathematics problems is not based solely on one's knowledge of mathematics. It is also based on metacognitive processes related to mathematics strategy usage, the emotions an individual feels when doing a problem and the personal beliefs of one's mathematical abilities (Garafalo & Lester, 1985; Schoenfeld, 1985; Mcleod, 1988).

For the purposes of discussion, beliefs will be defined as the personal assumptions from which individuals make decisions about the actions they will undertake. This notion is consistent with research that indicates that actions are motivated by what individuals perceive are the outcomes of their actions (Kloosterman, 1996). Students, in the process of learning mathematics, experience both positive and negative emotions, which influence the development of their attitude towards mathematics as a whole. These beliefs about mathematics, about what they need it for, and how strong they are as mathematics students are related to learning and can significantly affect what students do in a mathematics classroom (Kloosterman, 1996).

Teacher educators are charged with the daunting task of shaping and reshaping the attitudes, beliefs and content knowledge of preservice teachers. Teacher education programs must sometimes help participants to deconstruct, and reconstruct their views on teaching and learning (Brown & Borko, 1992; Wilson & Ball, 1996). It is important for mathematics to be learned in a supportive community of learners (Brown & Campione, 1994). This environment can also provide an arena for discussion of these important affective issues.

The authors' primary purpose of this research was to investigate the beliefs, attitudes and experiences that preservice teachers have had while learning mathematics. This paper will describe 1) students' perceived attitudes, beliefs and experiences related to teaching and learning mathematics 2) methodology we used to impact attitude of preservice teachers, and 3) future investigations for this research.

### **Methodology**

The first component of this research plan was completed by collecting data from preservice teachers, who planned to teach at either the elementary, middle, or secondary level, and were enrolled in a mathematics or mathematics education course required for students seeking teaching certification in their respective level. Data were gathered in the form of written responses called "Mathematics Autobiographies" during the first week of the semester. We requested that students respond in writing about any experience in mathematics that they felt contributed to their mathematical development. A total of seventy-two mathematics autobiographies were gathered from three different levels of college mathematics courses and two secondary mathematics education courses. In the second session of each of these courses students were asked to share with the class any experiences they were comfortable sharing, and then as a group we discussed the implications for mathematics instruction.

After analyzing the previous data, we collected baseline quantitative and qualitative data (both pre and post) from forty- one preservice elementary teachers regarding their attitudes, beliefs, and experiences. This data was collected at the beginning of the first course (Number Systems) and at the end of the second course (Concepts in Mathematics, Probability, and Statistics). In addition, we gathered qualitative data about how these prospective teachers view themselves as mathematics students; and, their thoughts on their future usage of technology, writing, and cooperative learning in the teaching mathematics.

Curricular modifications were made and implemented in the courses following baseline data collection. These changes include an increased emphasis on: 1) multiple concrete representations and appropriate conceptual models of mathematics, 2) cooperative learning and mathematical discourse, and 3) technology.

### **Concrete Representations and Appropriate Models**

Learners of mathematics who do not have exposure to concrete representations of mathematics may tend to view mathematics as a collection of abstract unconnected

topics. Through the use of manipulatives, preservice teachers are presented with a different view of mathematics. Our sequence provides preservice teachers with the opportunity to investigate mathematics through the use of concrete, pictorial and symbolic representations.

### **Cooperative Learning and Mathematical Discourse**

Mathematical discourse is one of the most important facets in preparing preservice teachers to teach mathematics. Effective teachers not only need to understand the concepts thoroughly, they also need to be able to discuss the mathematics in a way that is understandable to elementary-age children. Preservice teachers in our courses investigate mathematics daily, in a cooperative learning atmosphere that allows them to share their ideas with others as well as listen to different approaches used by their peers. Journal assignments are integrated so that preservice teachers are able to work on expressing their thoughts in writing and emphasize the importance of communication in mathematics.

### **Technology**

When including technology in a mathematics course, it is essential that one look at *why* and *how* technology is used. One of the goals in our three-course sequence is to use technology in meaningful ways, as a means to develop a deep understanding of a topic, not just as a tool to avoid computation. Technology is used as a tool to investigate concepts and real-world situations.

### **Data Analysis**

Analysis was completed on all data collected. Quantitative data were analyzed by computing statistical means and qualitative data were analyzed by conducting a comparison across all participants and coded according to emerging themes (Miles & Huberman, 1994).

### **Results**

#### **Mathematics Autobiography**

Mathematics autobiographies were written by K-12 preservice teachers at the onset of this research study. Presented below is a summary of key findings.

The following were found to be important in students' experiences learning mathematics: the role of the teacher; support and influence of family; challenge; issues of fear, failure and avoidance; learning strategies; and content issues. All of these issues mentioned are in some fashion tied to one variable, the teacher. Since the teacher generally guides classroom instruction, many of these issues focus on a teacher's approach to classroom instruction.

Typically preservice elementary teachers had more negative feelings, attitudes and less confidence toward learning mathematics. They felt that mathematics "was just not their strong suit", "was a horrible subject" and that they were "just plain stupid

at math” and thus “hated math.” These students also expressed their fear of their current mathematics class. In addition, they experienced increased failure in their entire mathematical experience from kindergarten through college.

Middle school preservice teachers felt some of the same anxiety as their elementary teacher counterparts. However, this anxiety was mixed with enough successful experiences in mathematics to encourage a greater commitment to the teaching and learning of mathematics. For the most part, their experiences in mathematics class were positive, although the love/hate relationship with mathematics was evident in their self reports: “As for my relationship with math today, I hesitate to call it dysfunctional, but it is definitely wrought with anxiety and at times exhilaration.”

High school preservice teachers’ memories of their mathematics classes were the least tainted by frustration and failure as depicted by this student, “I like to think I’ve always been good at math and never had to struggle.” They all spoke of influential teachers who helped them develop a love of math, teachers who also often singled them out and instilled a belief that they were talented in doing mathematics. They had a desire to emulate the characteristics of this beloved teacher. Many spoke of great admiration for their parents’ understanding of mathematics and the help they received growing up which helped them learn mathematics.

The major difference we found in each of these groups was in confidence level. It seems obvious that students who experience less failure would have more confidence in their abilities. The preservice elementary students generally reported more anxiety over learning mathematics. They also spoke, as a group, of more failure and self-doubt toward their abilities to learn and do mathematics well than secondary preservice teachers.

### **Attitude Data**

As part of our ongoing research project, we chose to focus on preservice elementary teachers enrolled in the mathematics for elementary school teachers course. Quantitative data were collected from students at the beginning of the first course and at the end of the second course. A total of forty-one elementary preservice teachers who took both courses consecutively completed both pre-course and post-course instrumentation. See Appendix A for the Instrumentation.

### **Future Teaching Methods**

At the beginning of the semester, students were asked to respond to the following: “Please describe how you would teach mathematics in an elementary classroom?” We found that responses to this question fell on a continuum, with one end of the continuum representing traditional teaching methods, the other end representing hands-on teaching methods, and the middle representing a group of preservice teachers that we consider to be emerging. A total of thirty-nine participants responded to this question (two left it blank); nine percent fell in the traditional category, thirty-seven percent

were in the emerging category, and fifty four percent were in the hands-on category. After two semesters of Mathematics for elementary school teachers' courses, Sixty-four percent of the teachers fell into the hands-on category, thirty-five in the emerging category and one percent in the traditional category. We describe the characteristics of the three categories below.

The "traditional" teacher is one who stated that their primary mode of teaching would be lecture. An emphasis was also placed on using a step-by-step, repetitive approach to teaching as opposed to a conceptually- based focus. One preservice teacher described their future classroom teaching in the following manner: "If I were to teach to an elementary classroom I would first lecture to the class, explaining the concepts, definitions, as well as going over previous problems on assignments, homework or quizzes. Afterwards, I would have every student try out a few practice questions that they will be working on that day."

The "emerging teacher" had many characteristics of a traditional teacher, yet also demonstrated a progression toward teaching in a conceptually-based manner. These individuals were more concerned with engaging their students in learning but they restricted the engagement to cooperative learning. They also placed some importance on representing material in a visual manner. One participant stated: "I would lecture in such a way that the students would be involved. After lectures, I would have games with the new material so that the student get practice with it (math concepts) in a fun way."

The "hands-on" teacher seems to be aware that students learn in a variety of ways, and that concrete representation is very important when first introducing a concept to students. These individuals focused on engaging their individual students in learning mathematics by using visuals, concrete manipulatives, and cooperative learning. Note the sharp contrast to the traditional teacher who focused on one presentation to the group of students but did not emphasize student participation and engagement. One preservice teacher in the "hands on" category described her vision of teaching mathematics in the following manner: "Use simple concepts to make it fun; collaborative and hands-on activities to teach math. In groups, pairs, and as a whole, whatever it takes."

### **Cooperative Learning**

Preservice teachers were asked about their experiences learning mathematics cooperatively and if they would use group learning in their future teaching. Ninety-five percent of the preservice teachers responded that they enjoyed learning mathematics cooperatively while five percent reported that they did not. An overwhelming ninety-five percent would teach their students using cooperative learning. Sixty-two percent said they had previously been involved in learning mathematics cooperatively, however, thirty-eight percent had not.

Among the ninety-five who enjoyed working cooperatively, the motivation differed. Some believe that cooperative learning sessions afforded them the opportunity to strengthen their understanding of mathematics by seeing other perspectives. Others used cooperative learning simply as an opportunity to get help with their mathematics homework.

Following completion of the two courses using cooperative learning techniques, all participants had experience with this method of teaching. Preservice teachers then responded that ninety-nine percent of them would teach using cooperative learning, and one percent would not.

### **Writing in the Mathematics Classroom**

Preservice teachers were asked about the role writing played in their learning of mathematics; if they had to explain their answers in writing in previous mathematics classes; and if they thought explaining their answers in writing would help them learn mathematics.

Prior to taking both mathematics courses, eighty-three percent of the participants stated that writing had been a part of their experience of learning mathematics, seventeen percent did not. Eighty-three percent thought explaining their answers in writing would help them learn mathematics, six percent did not and eleven percent were not sure.

As with cooperative learning, the courses these participants engaged in for two semesters were taught with an emphasis on writing. All participants had experience writing in the mathematics curriculum and ninety-four percent reported that they feel writing is important method of helping them learn mathematics.

### **Perceived Mathematical Ability**

We asked students to self report their mathematical abilities and whether they believed that a weak student could become a strong student. The participants described themselves on a continuum from a weak to a strong mathematics student. Seventy-four percent described themselves as weak students, twenty percent said they were average, and six percent said they viewed themselves as strong mathematics students.

Overwhelmingly, ninety-nine percent of preservice teachers stated a weak student could become a strong student, one percent said no. Several factors mentioned that participants believed would contribute to the strengthening of a student include practice, studying hard, determination and encouragement from a good teacher or tutor.

As in the pretest participants on the posttest described themselves on a continuum from a weak to a strong mathematics student. Twenty-four percent described themselves as weak students, sixty-three percent said they were average, and thirteen percent said they viewed themselves as strong mathematics students. They all stated that a weak student could become a strong student.

### **The Role of Technology**

Information was also gathered about preservice teachers' experience using technology in learning mathematics. And their responses to the following question, what role do you believe technology should play in the teaching and learning of mathematics?

Eighty-eight percent of our participants had previously used technology in learning mathematics, and twelve percent had not. The types of technology that were utilized were computers, graphing calculators, and non-graphing calculators. Preservice teachers were very specific about how technology should be used and the role it should play in teaching and learning mathematics. Most participants held a strong belief that calculators should not be used for basic math, that students should have a deep understanding of a concept before using the calculator. Overwhelmingly they were concerned with using technology without understanding; they did not want technology to be used as a crutch but as a learning tool.

All participants were exposed and engaged in learning mathematics using technology in both of the courses. Ninety-one percent of the participants viewed technology as an important component to teaching mathematics and eight percent believed that it was not a necessary component and should only be used minimally, especially in lower level mathematics such as elementary mathematics.

### **Quantitative Questionnaire on Attitudes**

A Likert-scale questionnaire on attitudes and beliefs was administered at the beginning of the first course and end of the second course. The same forty-one participants from the qualitative instrument completed the quantitative instrument. See Appendix B for the instrument. Although the instrument contains both positively- and negatively- worded questions, responses were ordered so that a higher mean represents a more positive attitude. Responses ranged from 1 to 5.

Data collected at the beginning of the first course suggest that the preservice teachers held a fairly neutral view on whether they liked mathematics and looked forward to taking more mathematics classes as well as whether they looked forward to teaching mathematics courses in the future. Slightly more positive responses were reported on the use of technology, the use of manipulatives, and the belief that mathematical topics are connected. Preservice teachers generally agreed that 1) understanding mathematics does not require special abilities, 2) technology is not only for slow learners, 3) investigating a problem is more important than getting the correct answer, 4) time spent thinking about mathematics is important, and 5) college mathematics courses are helpful for their future teaching of mathematics. For each respondent, a composite mean was computed from all responses, representing an individual's overall negative or positive attitude. They also believed that students must solve many problems following examples provided. The overall mean score for attitude was 3.57, representing a slight positive attitude toward mathematics.

Of the fourteen items, three resulted in statistically significant differences in mean values upon comparison of the questionnaires administered at the beginning and end of two mathematics courses. Students had a more positive attitude towards taking more mathematics courses, liked mathematics more, and believed more strongly that mathematics topics were connected to each other. In addition, preservice teachers' overall mean score on attitude increased significantly from 3.57 to 3.75.

### **Discussion**

Experts in attitudinal measurement warn of the difficulties of obtaining statistically significant differences in attitude over a relatively short time period, such as a ten-month period spanning two semesters. Yet many of us would like to believe that our courses have some long-term effects in preservice teachers' attitudes towards mathematics. Our study has provided us with some hopeful results. Recall that the quantitative instrument resulted in statistically significant differences in mean values for the following questions: I like mathematics, and I look forward to taking more mathematics classes. There was also a statistically significant difference on the item referring to the connectedness of mathematical topics. This significant difference indicates that students believe more strongly that mathematical topics are connected. The overall mean score from the questionnaire increased significantly as well. All of these significant differences suggest that students are having positive experiences in their mathematics for elementary teachers course sequence. The qualitative results corroborate this statement.

According to our qualitative data on attitudes, we have discovered that preservice teachers, at the end of two mathematics courses, have a much greater tendency towards hands-on learning in their teaching of mathematics. That can be interpreted as a positive reaction to the many experiences with hands-on learning provided in the preservice mathematics courses. Furthermore, preservice teachers responded that they would use a greater variety of teaching methods in their mathematics classes that they will teach including cooperative learning, writing, and technology. In addition, preservice teachers' confidence in their mathematical abilities increased substantially.

### **Issues for Discussion**

Overall, the data point to an improvement in attitude. Yet, we realize there are limitations to this study and that further research is needed. For discussion, we would like to focus on several issues, related to the following questions. First, how do we as mathematics educators positively impact preservice teachers' attitudes towards mathematics? Secondly, how do attitudes affect both the teaching and learning of mathematics? And lastly, what are best practices and research methods that can be used to effect greater visible change in attitudes and beliefs?

## How Do We Positively Impact Preservice Teachers' Attitudes Towards Mathematics?

Using *Principles and Standards for Teaching Mathematics* (National Council of Teachers of Mathematics [NCTM], 2000) and current research on best practices we designed our courses with a goal of developing a mathematical community of learners. The following sections describe techniques we have used to positively impact preservice teachers' attitudes.

### Development of a Mathematical Community

**Mathematics autobiographies.** Mathematics autobiographies can be used to facilitate a positive classroom environment, one in which all students feel that their experiences and background are valued. Sharing autobiographies in a classroom discussion can help students identify with others' similar experiences as well as enlighten students on the diversity of student backgrounds. For example, as our students shared their experiences, a common discussion that developed focused on difficulties learning mathematics. The discussion progressed into exploring a variety of different learning strategies used to learn mathematics. We have found that an important component of using mathematics autobiographies is having our students verbally share and discuss their experiences. Shared experiences begin to develop commonalities such that they begin to connect to one another and often realize they are not alone with their feelings, beliefs, experiences, and approaches toward learning mathematics. In addition, such discussions facilitate the development of a supportive mathematical community, one in which students can construct their own ideas, find their own representations, and connect mathematical ideas in their own ways while doing mathematics together. Students can share their work in a comfortable atmosphere where discourse and collaboration are valued (Brown & Campione, 1994; Bruner, 1996).

**Instructional strategies.** One premise in our research is the belief that engaging preservice teachers in mathematical investigations can bring about positive change in attitude. This belief brings into question the whole issue of what it means to "do" mathematics. A well-designed activity contains one or more of the following elements: 1) investigation of a mathematical concept; 2) cooperative learning; 3) connections to other mathematical concepts, other disciplines or real-world problems; and 4)-student discourse. In each of our courses concrete representation of each concept being taught is utilized before moving to the pictorial and symbolic representation. In addition, these concepts are investigated with technology when appropriate. Furthermore, preservice teachers investigate these topics through different lenses; first through the lens of a student and then through the lens of an elementary teacher. With such an activity, the focus is on active learning rather than passive reception. Furthermore, the emphasis is also

removed from the rote repetition of procedures and is shifted towards grappling with major concepts of elementary mathematics. It is the authors' belief that these activities serve a great purpose in redefining what mathematics is for these preservice teachers and the different ways it can be learned.

The strategies we implemented were based on National Standards (NCTM, 2000) and recent research. We are interested in making further curricular changes and pursuing other means to impact attitude.

### **How Do Attitudes Affect Both the Teaching and Learning Of Mathematics?**

Since prior experiences appear to have shaped preservice teachers' attitudes and self-efficacy about mathematics, it is important to consider how their experiences may affect their future teaching of mathematics. Although our preservice teachers did not explicitly mention the impact their learning experiences might have on their future teaching, we believe there is an impact. There seems to be a range in possibilities of how this might impact teaching. There is the possibility that these students may teach just as they were taught. Conversely, there is the possibility that preservice teachers, when taught using appropriate methodologies, may embrace these methods and utilize them in their own teaching. The impact that a positive or negative experience learning mathematics has on future teaching is an area that needs to be explored further. Without the opportunity to experiment with new methods of teaching and learning, to examine their own beliefs and knowledge (Kloosterman, Raymond, & Emenaker, 1996), teacher educators are likely to fall into past patterns of teaching and learning (Wilson & Ball, 1996).

### **What are Best Practices and Research Methods that Can be Used to Effect Greater Visible Change in Attitudes and Beliefs?**

In order to fully investigate teacher attitude, longitudinal studies need to be developed. We are interested in the attitudes of those teachers currently teaching mathematics; specifically, their attitudes, beliefs, and experiences with regard to teaching and learning mathematics. We would like to investigate preservice teachers' attitudes prior to their coursework and follow them through their first few years of teaching, measuring their attitude throughout this process. This information could be helpful when developing courses for preservice teachers and inservice professional development throughout a teacher's career.

Our data suggests preservice teachers' views of mathematics as a connected body of knowledge increased. As such we are interested in the possible connection between attitude and mathematical understanding. Specifically, we are interested in assessing the knowledge base of both preservice and inservice mathematics teachers and how they view mathematics and the connections between certain topics.

The onset of this study we began collecting data from 105 preservice teachers. At the end of the second semester, only forty-one students completed the second

(required) course in a three-course sequence to prepare preservice teachers. The initial data we collected was different for 105 participants, versus data from the thirty-nine who completed the second course in the following semester. Of significance to the researchers are several questions: 1) do the preservice teachers with more positive attitudes take the courses sequentially? 2) Would the results be significantly different if taken after the third course in the sequence 3) what is the impact on attitude if all three courses are taken at once or if they are taken over a longer period of time? 4) What are the best practices for assessing change in preservice teachers' attitudes'?

### Summary

As mathematics educators we believe it is essential for preservice teachers to have a positive attitude toward mathematics. Research supports our belief that future teachers need to have a positive view of themselves as mathematicians, and as competent future mathematics educators. First we need to identify their attitudes and then work to provide positive experiences that will effectively impact their future teaching of mathematics. We also need to insure that throughout their teaching careers they maintain a positive view of themselves as mathematicians and as effective teachers of mathematics. Further research in this area needs to be completed to successfully achieve this goal and support our future mathematics educators.

#### **Appendix A: Qualitative Instrumentation**

1. Please describe how you might teach mathematics in an elementary classroom (e.g., how would you instruct students, lecture, use cooperative learning, etc.).
2. Do you enjoy learning mathematics while working in groups? Would you teach your classes using group work? Have you previously been taught mathematics while learning in groups?
3. What role, if any, has writing played in your past learning of mathematics? Have you had to explain your answers in writing in previous mathematics classes? Do you think explaining your answers in writing will help you learn mathematics?
4. How would you describe your mathematical abilities? Explain. Do you believe a weak student can become a strong student? Explain your answer.
5. How much have you previously used technology in learning mathematics? What role do you believe technology should play in the teaching and learning of mathematics?

#### **Appendix B: Quantitative Instrumentation**

Below, there is a series of sentences. Indicate in your bubble sheet the degree to which you agree or disagree with each sentence. There are no right or wrong answers. The correct responses are those that reflect your attitudes and beliefs .

A Strongly Agree B Agree C Not sure D Disagree E Strongly Disagree

1. I am looking forward to taking more mathematics courses.

2. I enjoy learning how to use technologies (e.g., calculators, computers, etc.) in mathematics classes.
3. I like mathematics.
4. In grades K-9, truly understanding mathematics in schools requires special abilities that only some people possess.
5. The use of technologies (e.g., calculators, computers, etc.) in mathematics is an aid primarily for slow learners.
6. Mathematics consists of unrelated topics (e.g., algebra, arithmetic, calculus, and geometry).
7. To understand mathematics, students must solve many problems following examples provided.
8. Students should have experiences manipulating materials in the mathematics classroom before teachers introduce mathematics vocabulary.
9. Getting the correct answer to a problem in the mathematics classroom is more important than investigating the problem in a mathematical manner.
10. Students should be given regular opportunities to think about what they have learned in the mathematics classroom.
11. Using technologies (e.g., calculators, computers, etc.) in mathematics lessons will improve students' understandings of mathematics.
12. I expect that the college mathematics courses I take will be helpful to me in teaching mathematics in elementary or middle school.
13. I want to learn to use technologies (e.g., calculators, computers, etc.) to teach mathematics.
14. The idea of teaching mathematics scares me.

## THE NATURE AND FUTURE OF CLASSROOM CONNECTIVITY: THE DIALECTICS OF MATHEMATICS IN THE SOCIAL SPACE

New theoretical, methodological, and design frameworks for engaging classroom learning are provoked and supported by the highly interactive and group-centered capabilities of a new generation of classroom-based networks. This discussion group situates networked learning relative to a dialectic of (1) seeing mathematical and scientific structures as fully situated in socio-cultural contexts and (2) seeing mathematics as a way of structuring of our understanding of and design for group-situated teaching and learning. Acknowledging (1), significant classroom examples are then used to illustrate the reciprocal process (2) of mathematics structuring the social sphere (MS3). The mathematically informed ideas of *space-creating play* and *dynamic structure* are then used to update our ideas of generative teaching and learning and to situate these classroom examples. Then, returning again to the dialectic, this current work is critiqued from a socio-cultural perspective (1). *Participation* and *agency* are highlighted in this critique. The session closes with a discussion of future possibilities for classroom connectivity.

The highly interactive and group-centered capabilities of a new generation of classroom-based networks are helping both to support and to provoke the development of new theoretical, methodological and design frameworks for engaging classroom learning. This discussion group situates networked teaching and learning relative to a dialectic of (1) seeing mathematical and scientific structures as fully situated in socio-cultural contexts and (2) seeing mathematics as a way of structuring our understanding of and design for group-situated teaching and learning. The idea is that if mathematical and scientific structures are seen to fully participate in the social plane, then not only are they structured by the social plane (i.e., (1)) but they also structure social activity (i.e., (2)), including learning and teaching. Due to the group-focused interactivity and data collection capabilities of next-generation networking, we now

have a new tool to explore the dynamics of—and design for—classroom learning. A number of projects have responded to the challenge of learning in a network space by using mathematical/scientific ideas to organize and analyze classroom activity. Some of these recent projects focus on student learning and one is focused on teacher understanding. All of these projects have begun to use mathematics itself to organize their classroom-based work. This use of domain-related “big ideas” to organize and analyze group learning is what is meant by mathematics structuring the social sphere (MS3). The mathematically informed ideas of *space-creating play* and *dynamic structure* are then used to update our ideas of generative teaching and learning and to further situate the previous classroom examples. Our argument is that to take full advantage of these notions, and of the new classroom tools, researchers and educators must acknowledge explicitly the dialectic that exists between the domains of mathematics or science as structuring agents and the structuring functions of the social, cultural, historical milieu in which classroom learning and teaching in the domains exist. Returning again to the dialectic, this current work is then critiqued from a socio-cultural perspective focusing on ideas of participation and agency. Consistent with this dialectic framework, an overall notion of what is called generative teaching and learning is clarified in a way that both draws on previous work and uses the mutually constitutive relations captured by the dialectic for extending the prior analyses.

### **What’s New about Next Generation Classroom Networks**

This paper is not about technology *per se*, but rather about a specific instance of the interaction and co-evolution of design, technological affordance, and cognitive theory (Dewey, 1938; Hickman, 1990). Networks and ideas of generative teaching and learning can be and have been discussed without specific reference to technology (Wittrock, 1978, 1991; Learning Technology Center [LTC], 1992). The idea is that next generation networking can better support or “resonate” with generative practices and also, in iterating back to theory, allow us to further develop our ideas of what generativity is. To start this conversation, we may need to understand first how these new network designs are functionally evolved, and thus distinct, from the kinds of networking that has been with us for a long time. In this section the question becomes: What might be said to be “new” about next-generation network functionality in classrooms?

With a few important exceptions (among them, *CSILE*, associated with Scardamalia (1993); Scardamalia and Bereiter (1991); Scardamalia, Bereiter and Lamon (1994); and Scardamalia, Bereiter, McLean, Swallow and Woodruff (1989); collaborative notebook associated with Edelson, Pea and Gomez (1996); *ClassTalk* as discussed by Abrahamson (1998); Mestre (1996), or Hake (1998), or some of the projects discussed herein), networking in the classroom has served primarily in two ways: (i) As a portal to sources of information or interactivity having their “centers of balance” outside the classroom (e.g., visiting the *CNN* web site or filling out a web-based

questionnaire), or (ii) To implement Computer Assisted Instruction (CAI) or tutoring environments. Two top-level features characterize these uses of networking in classrooms. First, the experience is fundamentally individual – most of the activity could be carried out at home or in a local library as little or no use is made of the social space of the classroom. Second, the knowledge and/or the trajectory of learning is owned by someone who is not a member of the classroom (e.g., a distant “expert” for web content or the computer programmers for CAI/tutoring environments). Especially for low socio-economic status (SES) students who have had their experience of school-based technology skewed heavily toward the use of CAI environments, a fundamental message of mathematics and science reform—that the classroom should be a community of inquiry characterized by joint ownership and construction of understanding—is undermined. Traditional uses of classroom networks place the locus of knowledge making outside the classroom (even as the individual experience is often described as highly “customizable”).

The next-generation network functionality, provoking a new round of theorization and design, does mark a significant break with this tradition in terms of pedagogical vision and technical capability. To begin with, these systems are typically designed “from the ground up” with the classroom in mind. Rather than constrain the learning experience to be narrowly individualistic, this technology supports socially situated interaction and investigation. Moreover, the learning trajectories and the processes of knowledge construction are owned by the group itself. Software and hardware work together in supporting this “group-oriented” design. A significant number of these networks are about to become widely available and are poised to become a major presence in classroom learning. The implementations may vary but at the top level the design features of these systems are remarkably similar and typically include: individual devices or “nodes” that are relatively unobtrusive; the network supports a range of topologies for real-time or near-real time interaction (peer to peer, peer to group including whole-class, or group to group); the network is “wireless” and hence very flexible and portable; there is a core set of meaningful functionality in each device (e.g., at least that of a graphing calculator); there is a mixture of public and private display spaces (e.g., the public space can be a computer projection system as with participatory simulations (Wilensky & Stroup, 1999) or a calculator Viewscreen™ with the SimCalc materials (Kaput, Roschelle, Tatar, & Hegedus, 2002) and the private space can be the students’ own individual displays on a calculator, Palm Pilot™ or laptop computer); the network experience is “author-able” in that it allows teachers or others to create new activities; the network can readily support the exchange of a range of kinds of both group and individual artifacts/data-types including text, strings, numeric values, ordered pairs, lists, matrices, individual and whole class graphs, images and, in some cases, sounds or video; and the network enables new (as well as old) forms of gesture (e.g., turning to the left with an arrow key on a calculator).

An interesting facet of working with these kinds of networks is how traditional

research methodologies and theories, based on some notion of simply “scaling up” to the group methods and models based on individual cognition, are overwhelmed. This kind of challenge has always been present in analyzing classroom learning, especially as we move toward a reform-based ideal of classrooms being communities of inquiry (Brown & Campione, 1996). The theoretical and methodological disconnect seems even more pronounced for researchers attempting to make sense of what happens in these highly interactive networked spaces. All the projects discussed in this paper are struggling to situate and organize what they are doing in terms of activity design, learning theory, and research methodology. The good news is that new patterns of analysis and design are beginning to emerge. One of these new frameworks is the use of mathematical ideas not just as “content” to be learned but also as an interpretive framework for learning analysis and activity design. This is what will be discussed as mathematics structuring the social sphere (MS3). And then, in turn, the mathematically informed ideas of space-creating play and dynamic structure are used to clarify and update our understandings of generative teaching and learning. Here we can begin see how technological affordance can loop back to change the shape of cognitive theory and activity design. Returning to the dialectic, we then use insights from a socio-cultural perspective to critique and extend the ideas of participation and agency related to generative teaching and learning.

### **Mathematics Structuring the Social Sphere: Examples From Networked Classrooms**

During a recent session at the Annual Meeting of the American Educational Research Association, a group of investigators presented results from working in classrooms with this kind of next generation classroom network (Kaput, Roschelle, Tatar & Hegedus, 2002; Mack, 2002; Stroup, 2002a, 2002b; Wilensky). A striking features in common to these presentations was the way in which ideas from mathematics proper were either starting to become, or already were, central to the organization of their work. This engagement with mathematics went well beyond thinking of it as content to be learned by individual students. These presentations are discussed briefly in this paper as part of helping us understand what it might mean to think of mathematics as a socially structuring tool in learning research and design. These examples illustrate how thinking of mathematics as an active participatory agent in social activity, might be considered a reasonable “next step” in our ever-evolving understanding of the nature of mathematical and scientific activity itself. That is, once we relinquish the assumption of the truly solitary mathematical or scientific researcher – as either a practical possibility or theoretical ideal – we are then free to fully engage how mathematics is a socially structured form of activity (part (1) of the dialectic). With this freedom also comes the possibility of investigating how mathematics is, or can be, socially structuring (part (2) of the dialectic). Each of the research efforts discussed in this section is responding to the challenges of creating learning activities in next

generation networks. Each illustrates the directions being taken in trying to say something meaningful about the learning and teaching that takes place in relation to these activities.

### Parametric Space

Moving their work from developing software for learning calculus ideas with individual computing devices to now situating the use of this kind of functionality in a network space, Jim Kaput, Jeremy Roschelle, Deborah Tatar and Stephen Hegedus from the SimCalc Project have been pushed to think anew about the design of the activities themselves (2002). Prior to the availability of classroom connectivity, they had presented students or small groups of students with individual learning tasks related, for example, to giving in advance a *velocity* graph that controls the motion of one animated character and then asking them to author a *position* graph for a second character such that its motion would now match that of the given character (thereby using the simulation and graphs to obtain the integral of the original velocity function). Given the network, they have begun to use the idea of a parametric space to organize the network-supported activity.

For example, in the curricular context of linear functions in  $y = mx + b$  (slope-intercept) form, to help understand the roles of the “m” and “b,” each group of students is assigned its own value of “b” (the y-intercept), which controls the starting point of the group’s “mascot” in a “race.” In this race they are asked to finish in a tie with all the other groups’ mascots at a given time (six seconds) and position (twelve meters). They then must determine the velocity (and hence slope) that accomplishes this task for their given initial conditions. In submitting their solutions to a public display space the resulting aggregation of graphs has properties that none of the individual graphs have: A “star” of lines all meeting at the same place is created. When simulated characters associated with each of these lines are animated, the characters all come together at (6, 12) and, if continued for an additional two seconds, they then spread apart again in a kind of mathematical dance. In this way, the SimCalc Project has begun to use the mathematical idea of parametric space as both the “content” and the cognitive organizer for the network-supported learning activity to raise the level of organization of mathematical objects as well as the focus of mathematical attention in the classroom. For further specific examples, see Kaput & Hegedus (these proceedings).

### Proof

In a related way, Andre Mack (2002) has begun significant network-based research related to how teachers’ notions of mathematical proof structure and organize their real-time decision making about where to “go” with the classroom learning, especially as related to moments of mathematical uncertainty (e.g., when students ask questions that the teachers (and/or the students) are uncertain about). Just as moments of uncertainty in mathematics proper provoke a need to construct proofs, some idea of

how valid reasoning “works” in mathematics animates teachers’ organization of learning in their own classrooms. Teachers’ notions of aesthetics for mathematical proof serve as an instructional resource for making sense of and validating (or disproving) student-generated mathematics claims. A wide range of understandings of mathematical proof is represented in Mack’s investigations. What is important here is the way in which the mathematical idea of proof is used to organize his analysis of classroom learning. Much of this work moves well beyond traditional understandings of pedagogical content knowledge (Shulman, 1987) centered on the interaction of pedagogy (typically understood as *how* to teach) and content (understood as *what* gets taught), the content—proof in this case—*becomes* or is *enacted* as the pedagogy in moving to the group as the unit of learning analysis.

The network-supported activities bringing about significant instances of uncertainty in the classroom include participatory simulations (discussed next) where, for example, each student uses the arrow keys on a networked calculator to move an individual point around on his/her screen. At the same time, this point and all the others from the class move on a computer screen projected at the front of the class. The teacher asks the students to move according to a rule like “move until your y-value is two times your x value.” When a line forms, the points are then aggregated and sent back to the students with the challenge using the calculator to find equivalent functions that go through these points. The student functions can then be collected and displayed (Wilensky & Stroup, 1999). Mack has found (2002) that often, in the course of this activity, students will submit functions where the teacher is unsure of their equivalence. The teacher then has to make decisions about how to proceed based on his/her notions of how proof works in mathematics. The trajectory of the group learning experience is structured by the teacher’s ideas of how mathematics reasoning is carried out.

### **Complexity**

In a similar way, content becomes pedagogy for the Participatory Simulations Project (Wilensky & Stroup, 1999). Participatory simulations are activities where learners act out the roles of individual system elements and then observe how the behavior of the system as a whole can emerge from their individual behaviors. These emergent results then become the focus of in-class discussion and analysis. Using network technology with a public display space, students can, for example, become agents in a population where a disease is introduced and be part of the system when the disease spreads. Or they can control a stoplight in a simulated city’s traffic grid and work toward improving the traffic flow. Not only is dynamic systems modeling the content being introduced into the curriculum but also the learning itself is organized in terms of the classroom *becoming* the dynamic system. By assuming roles in a system, mathematical ideas like emergence, feedback, and complexity are literally embodied by the network-supported learning activity. The traffic control or “gridlock” activity

helps to illustrate both how students already have ideas about how complex systems may work and how – in using this embodied learning activity – students develop significant insights and conjectures related to emergent phenomena like traffic.

When introduced to the gridlock activity, students are presented with the following scenario: The mayor of the City of Gridlock is unhappy with the traffic congestion in town and she has commissioned the class to improve the situation (Wilensky & Stroup, in review). The goal of the activity is for the students to find ways of optimizing traffic flow for the simulated city. The Gridlock activity has been run in a variety of settings, from middle school science classrooms, to secondary social science classrooms, undergraduate and graduate education classes, and at research conferences. The responses reported below are from one of these instances of running the activity in a class made up of twenty-four seventh graders taking science at a relatively low income, ethnically/racially diverse school located near Austin, Texas.

After the goal of the activity was introduced students are asked what they know about traffic flow. In response to the teacher asking, “What are some of the things that you guys listed that would be indications that traffic would be good or bad to you?,” the students presented ideas that covered more than two chalk boards. Ideas ranged from “slow drivers” and “barrier walls too close for cars” to “too many cars” and “special events” like “crashes.” The sense is that learners can articulate a wide range of factors that can impact complex phenomena like traffic. Some of these responses are behaviors of individual drivers and others are related to the structure of the roadways or the context for the behavior (e.g., lights too long). Taken collectively, these lists suggest that learners do have an initial appreciation of how agent behavior in an environment can have consequences for the emergent features of a complex system. For traffic this insight comes from their first-person experience. Part of the purpose of participatory simulations is to leverage the learners’ first-person perspective in a way that can lead to more robust, incisive and powerful understandings of complex phenomena.

Next the students engage in the participatory simulation using the network. After a number of rounds of “play” starting with getting familiar with controlling the lights and then moving to improving the traffic flow, the teacher stopped the class and asked:

Teacher: Has anybody started to think of some ideas like what are you doing at your stop light that you think is working really well? Who has some ideas of why they think maybe their stoplight is working better than somebody else’s stoplight. Anybody have any ideas? Anything that you’re trying to do yet? Yeah (pointing to student).

Student 1: Letting one go and then the other go.

Teacher: Okay, so you’re letting one go ... are you letting it go for a certain amount of time?

Student 1: Nah, just go this and that way.

Teacher: So you're just doing one then enter, two then enter....

Student 2: Pick a space between the line of cars to turn the light red, so that way, so then all the cars will be stuck together.

Teacher: So get the cars staggered and spaced out and pick a spot between ... yes, sir (pointing to a third student).

Student 3: Have it like every place where I saw the cars go like this (gesturing downward) and once they're done have them all go like that (gesturing to the side).

Teacher: So have the down ones green (gesturing downward with fingers extended) and then all the side-to-side ones green (similar gesturing to the side).

These are just some of the strategies students generate. The first strategy is simply alternating the lights at a regular interval. The second strategy looks for open spaces to shoot for in turning the light red in that direction. Other sections of classes at this school articulated what we call a "traffic cop" strategy where you simply look locally to see in which direction there are the most cars at your intersection, and then let that direction go (i.e., like what a traffic cop might do at a busy intersection). Some students discussed the possibility of developing "smart cars." With smart cars there might not be a need for lights, *if* a way could be found to "coordinate" with cars coming from the "other" direction. As is true for all the groups we have worked with, the Austin area students came up with a phase-related strategy for "synch-ing" the lights. The actual classroom exchange related to this strategy highlights some of the pedagogical challenges related to engaging and extending the developing strategies of students. These issues help point to possible future directions for developing the HubNet functionality and are under development.

### **Self-Organization**

In a closely related line of research based on using participatory simulations (Wilensky & Stroup, 1999), Andy Hurford is looking at the learning in a network through a "self-organizing, critical systems" (SOCS) lens (1998). SOCS characterizes both the behavior of the simulated system and the learning that occurs in relation to *living in* that system. Bak and Chen (1991) provide an accessible real-life example of a SOCS and identify some general attributes of these systems. SOCS are: 1) sensitive to initial conditions; 2) scale invariant; 3) self-organizing; and 4) evolve in a way that may be characterized as a one-over-f distribution (Bak, & Chen, 1991, p. 48). SOCS are said to be "critical" because they alternate between relatively stable and relatively chaotic phases (Peterson, 2000). An application of SOCS theory to a learning system

where learning was defined in terms of reorganization of individuals' conceptual structures (Hurford, 1998) argued that the first SOCS attribute, sensitivity to initial conditions, might be compared with the importance of prior knowledge in learning. That is, what one learns depends upon what the student knows—learning is sensitive to initial conditions. Conceptual reorganizations may occur in many sizes from small “ahas” to grand gestalt moments (Strike & Posner, 1992; Demastes, Good, & Peebles, 1996; Kuhn, 1996) and large reorganizations “look” just like small reorganizations except for their scale. Self-organization, “a process in which pattern at the global level of a system emerges solely from numerous interactions among the lower-level components of the system... executed using only local information, without reference to the global pattern” (Camazine, Denoubourg, Franks, Sneyd, Theraulaz, & Bonabeau, 2001, p. 8), is what happens as the learner interacts with the subject matter. In this analysis it is the learner's conceptual structures, evolving according to the learner's own sets of rules and in the individual's unique context that are self-organizing. The final attribute of a SOCS as discussed here is the notion of a one-over- $f$  distribution, and here we can only assert that conceptual change may actually occur as a “continuous spectrum of learning events” (Hurford, 1998, p. 21) that may be characterized by the distribution function.

Although the above example is based on an investigation of individual learning, SOCS are scale-invariant, and as such, the model contends that learning should be self-similar across several orders of magnitude. Hence it seems reasonable to assume that learning in an individual and learning in small groups, classrooms, or school systems should share significant similarities. Beyond this attribute of self-similarity the fundamental assumption of this research is that learning can be profitably viewed as a SOCS, and all self-organizing critical systems share attributes as described above. The challenge now is to “watch” for these SOCS attributes in classrooms and to use that information to promote student learning. At least initially the justification for attempting to look at learning through a SOCS lens is based on a plausibility argument: In contrast to viewing a classroom as the simple linear summation of the individual learning units, it seems at least plausible that 1) the classroom is better understood as a complex dynamic system and 2) that a SOCS perspective might stand to “fit” as an account of this complexity. This “plausibility” argument is similar to that advanced at an early stage of theory development in other areas of cognitive science (Riesbeck & Schank, 1989; Kolodner, 1993). In now moving beyond the individual, SOCS rubrics and real-time computational tools are being developed for use with network-supported participatory simulations. The network functionality can carry out simultaneous analyses of student activity, such that it should be possible to look for SOCS signatures at various learning scales *while students are engaged* in network-mediated participatory simulations. Next generation connectivity can support new, real-time, analyses of student learning.

### MS3 Overview

What all these projects have in common is a sense in which mathematics is more than content. In the social space of network-supported interactivity, mathematics is seen as structuring the classroom activity and the related learning. A way of situating this development is to say a “next step” may follow from accepting that mathematical and scientific learning is fully socially situated. The insight that learning is socially situated has – certainly in the last twenty years – brought to the table of learning analyses perspectives and approaches from disciplines as diverse as anthropology, sociology, ethnic studies, and critical theory. Methodologically, case studies and ethnography have become commonplace both in analyzing scientific activity itself, and in making sense of interactions in math and science classrooms. The inclusion of social analyses has heralded a new era of not just greater subtlety in the ways we look at learning, but also in what it means to learn. Learning has come to be understood as a form of participation in activities and processes much larger than individual comprehension. In a related way, the design of classroom activity is being increasingly situated relative to socially-derived frameworks and analyses. Many learning researchers now embrace the idea that cognitive structures or big ideas exist in, and as a result of, social activity.

What may follow as a next step in this analysis, then, is this: If mathematical ideas participate fully in the social space, they are not just *organized by* the social space they are also *organizing of* this social space. Just as the move to situating mathematics and science in the “larger” social plane brought new theoretical, methodological, and design perspectives to the table of understanding learning, so too the move to seeing mathematics as structuring of social space may invite to the table perspectives from, among others, formal mathematics, complexity theory, mathematical biology and computer science. Extending this MS3 idea to previously existing ideas of generative teaching and learning allows us to add new facets to activity design and learning theory, especially as they come to be supported by next generation networks.

#### Updating Generative Teaching and Learning from an MS3 Perspective

We begin to move from that part of the dialectic focused on using mathematics to structure the social space (2) to use mathematically informed ideas of space-creating play and dynamic structure as a way to move back to situating mathematics in the social sphere (1). In a sense, this analysis of generativity begins to situate these various projects relative to the dialectic of mathematics in a social space. To be sure, models of generative teaching and learning have been around for a while. Some aspects of space-creating activity and dynamic structure are nascent in previous analyses of generativity, but this paper is pushing to make these ideas more visible and more explicitly about designing for highly interactive group spaces.

Generative teaching as discussed by Wittrock is “a model of the teaching of comprehension and the learning of the types of relations that learners must construct

between stored knowledge, memories of experience, and new information for comprehension to occur" (1991, p. 170). What Whittrock means by the learners' active construction of new "relations" is close to what we might call constructivist teaching pedagogy. Consequently, generative learning in his framework involves students' ability to create artifacts that embody their constructed understandings. In a closely related way researchers from the Learning Technology Center at Vanderbilt emphasize aspects of creating "shared environments that permit sustained exploration by students and teachers" in a manner that mirrors the kinds of problems, opportunities, and tools engaged by experts (1992, p. 78). Teaching involves "anchoring or situating instruction in meaningful, problem-solving contexts that allow one to simulate in the classroom some of the advantages of apprenticeship learning" (1992, p. 78). Extending these practices to the new functional capabilities associated with next generation networking may push us to update these existing ideas of generative teaching and learning. Although each of these previous theories is generative at the level of the individual learner (or even at the level of a small group) there is not enough of a picture of how to structure the cross individual or cross small-group learning. Using mathematically structured ideas to organize classroom learning helps us to augment these understandings of generative teaching and learning in ways that can be well-supported by next generation network capabilities. Moreover this update is intended to include a wider range of activities and allow for greater precision in saying what it means for learning and teaching to be considered "generative." Using an MS3 stance the ideas of *space-creating play* and *dynamic structure* are highlighted.

### Space-Creating Play

In a technical sense mathematical "space" refers to, "An arbitrary collection of homogeneous objects (events, states, functions, figures, values of variables, etc.) between which there are relationships similar to the usual spatial relations..." (Union of International Associations, 2002). If students are asked to create and display functions that are the "same as  $4x$ ," they are generating a *space* of homogenous objects. In a network, this space is the result of students' play-full explorations of possibilities, using their individual computing devices, and then using the network to share one's own examples and learn from the examples of others. Worth emphasizing is the fact that play is not an "anything goes" state of affairs. Indeed, when considered carefully, "anything goes" is not usually a reasonable account of how play actually works for children:

The premise that Durkheim, Vygotsky, and Piaget share ...is that thinking and cognitive development involve participating in forms of social activity constituted by systems of shared rules that have to be grasped and voluntarily accepted. ... The system of rules serves, in fact, to constitute the play situation itself. In turn, these rules derive their force from the child's enjoyment of, and commitment to, the shared activity of the play-world (Nicolopoulou, 1993, p. 14).

Thinking and cognitive development related to play involve participation: the activity is structured by a “system of shared rules” that need to be “grasped” and “voluntarily accepted.” The power of this form of activity comes precisely from the children’s “enjoyment” and “commitment” related to being part of the “play-world.” Generative teaching and learning as discussed earlier has had this space-creating play aspect, but it has been implicit in a way that has not utilized the “space” of potential mathematical behaviors and artifacts. The student-centered projects discussed earlier (Section 3.0) advance a sense in which learners “play” in an activity “constituted by systems of shared rules.” In turn, this participation creates a space of objects or emergent behavior that embodies students’ understandings of the mathematical or scientific content.

### Dynamic Structure

When students in a networked space create and then display functions that are “the same as  $4x$ ,” the structure of the activity is itself *lived* or brought into being by what the learners do. Unfortunately in mathematics research in particular, the idea of structure has come to be understood in a relatively static way. “Process-object” analyses of mathematics learning have tended to view “structure” as a relatively static kind of object. Social constructivists have tended to respond critically to this idea of structure.

When Soviet psychologists speak of the ‘structure of an activity,’ they have in mind something very different from what has come to be known as ‘structuralism’ in Western psychology (and mathematics education). The units are defined in terms of the function they fulfill rather than of any intrinsic properties they possess (Wertch, 1979, p. 19).

*Dynamic* structure is intended to point to a functional or operational sense of structure, not fixed or intrinsic attributes. A space of functions is created by the “ $4x$ ” activity, and in a significant sense this space is animated by the learners’ understanding of the mathematical ideas of equivalence. Their mathematical ideas are what *dynamically structure* their learning activity. This socially situated understanding of structure fits well with the ideas Soviet psychologists – and especially Vygotsky (1934/1962) – bring to learning. What may come as a surprise to some, however, is the sense in which this “lived” and larger-than-the individual meaning of dynamics structure may be exactly what Piaget (1970) was pointing to in suggesting constructs like the algebraic group could serve as the “prototype” of what he meant by cognitive structure. Structure, understood in this dynamic way, is a *patterning* or *coordination* in the kinds of operations on elements of the system. It is this larger dynamic sense of structure that allows Piaget to talk about group learning as “co-operation” (Montagnero & Maurice-Naville, 1997, p. 140) and may be what qualifies Piaget as the first major learning researcher to think of mathematics as structuring the social experience of coming to know. Viewed this way, there are striking parallels and forms of complementarity

between Vygotsky's analyses of language and Piaget's analyses of operational thought that can be brought to the task of thinking about, and designing for, activity in classrooms supported by next generation networked functionality. Generative learning and teaching come to be understood as organized by space-creating play and dynamic structure.

### **Generative Teaching and Learning from a Socio-Cultural Perspective**

This paper proposes that exploring the dialectic that exists between mathematics as a socially constructed domain and the domain-structured, concrete activity of teachers and students in math and science classrooms (MS3) provides researchers and educators an important framework for understanding the implications for design, pedagogy, notions of content, and research methods in classroom-based networks in particular, and classroom teaching and learning more generally. The projects reported on earlier represent important examples of the unique affordances of such networks and designs in that they highlight one aspect of the dialectic, namely the structuring of the classroom social space by mathematics or science proper. However, concomitant examination of these projects in terms of how mathematics is socially constructed by students and teachers engaged in sociocultural activity is necessary to extend the prior analyses of generativity within this framework.

Acceptance of the social construction of mathematics that results from the interactions of teachers and students with content, and with each other, affords a particular, powerful understanding of the nature of what is learned and taught in classrooms. It is also necessary to situate those interactions and the domain more explicitly and in more sophisticated ways within sociocultural activity to truly capture these complex phenomena. Many of the projects using networked classroom environments are focused on traditionally underserved students (e.g., students of color and/or living in poverty), but such things as historical notions of teacher, student, and content (Moll, 1990; Wells, 1999); cultural ways of knowing, interacting, and communicating (Gay, 2000; C. Lee & Smagorinsky, 2000); and the mediating function of language (Vygotsky, 1987; Wertsch, 1991) are under-specified. Thus, agency and participation; what kind of mathematics or science gets constructed, how, and by whom; and the mutually constitutive relation between structure and language need to be more fully elaborated. With this criticism we look to highlight opportunities to build on the important benefits inherent in a focus on the dialectic between mathematics or science as a domain that structures activity and the sociocultural activity through which mathematics or science is constructed. The work described herein does represent significant advancement relative to levels of agency and participation but in each we need to push again relative to situating mathematics in a richer sense of socio-cultural analysis.

### **Levels of Agency**

As detailed earlier, students' opportunities to assume agency in these new classroom social spaces are markedly different from traditional classrooms. Certainly, to

be a visible and necessary participant in public construction of knowledge entails a significant form of agency that has been largely missing in mathematics/science classrooms.

Recent work by Sarah Davis looks to make visible some important aspects of student and teacher agency. In the networked classroom, students can submit responses to be considered by the class without their identity being associated with that information. Both a sense of “that’s me” and a “right level” of anonymity combine to give students new forms of agency and situated identity. Anonymity facilitates the ability to explore mathematical behaviors in a non-threatening way. Freed from *who* sent in a response, students are able to explore *what* the mathematical activity represents, whether it is sending in functions that are the same as  $4x$  or controlling a traffic light in a simulation. Davis has found this anonymity helps advance both the students’ and the teachers’ sense of agency.

From the teacher’s perspective: “It just promotes a lot of discussion and everybody’s free to discuss it because kids can be criticizing an equation that they themselves wrote and nobody would know” (Davis, 2002). Students identify with their responses, icons, and data that show up in the group display. As can be seen in the next quote, in time the representation of self in relation to the group space can give the students a sense of how they are doing relative to the class as a whole.

Interviewer: Does that, in the other classes where you don’t know how other people are doing (Student 12: Right), you don’t know if you’re the only one (Student 12: Right), does that raise your anxiety level any...?

Student 12: Yeah it’s scary, because I think I’m the only one...I’m looking at my test, I think I’m the only one who got a 60 or whatever. And the couple of kids around me I’ll know what they got but then I have no idea how anyone else is doing, because it’s all privately done. Not that I need to know their test grades, but I’d like to know, how I stand. Am I the only one who needs help? And then you feel embarrassed to be the one raising your hand all the time, be the one staying after class because you think you’re the only one. So, here, it’s a lot more comfortable. You’re not embarrassed in front of the other kids. (Davis, 2002)

The ability to gather responses on all questions from all students gives important knowledge to the teacher. That knowledge then gives the teacher options for how to proceed in class. And again from the teacher’s perspective:

It’s great to know, where the kids are, actually it’s not always great because sometimes it’s pretty depressing to see where the kids are. There was something I did this year in one of my classes and I asked if there were any—I thought I had done a fine job—I asked if there were any questions, nobody had any questions and I just had an inkling, And I said okay well log on and lets check. And I believe two kids got it right so obviously they didn’t have a clue what they were doing and I went back and

re-taught. (Davis, 2002)

Agency here includes opportunities for both the teacher and students to anonymously reflect on and situate their respective states of understanding. Understanding centers both on the construction of content as such and, just as importantly, on “where everybody is” individually and collectively.

As significant an improvement as all these network-supported forms of interaction are—where historical notions of teachers’ and students’ relation to content are challenged—historical notions of content itself are still being maintained, tacitly, in the work to date. One might observe that an under-examined, embedded assumption is that math is homogeneous, monolithic; there is no ambiguity in what math is. The very notion that mathematics is socially constructed, especially given attention to the concrete, localized construction processes in classrooms, problematizes that homogeneity or lack of ambiguity. Viewed in this way, even an updated notion of generativity can become an aspect of classroom activity that serves only to lead to a predetermined outcome, rather than something that produces potential insights and growth possibilities for both actors *and* content. Generativity needs to be pushed to have us become more open to the possibility that what it is that ends up mattering to a group, and how this comes to be understood, might not have a greater point of comparison other than that of the group’s co-constructed agency.

### **Participation**

Careful consideration of what kind of participation in the construction of what kind of content is important so that classroom learning is generative in the sense that students not only learn in ways that foster powerful, dynamic understandings of mathematics, but that they develop knowledge and skills that foster their successful participation in mathematics in the larger world. If one of the aims of these projects is to open mathematics and mathematical reasoning to students, particularly students who have traditionally been under-served, in more powerful ways, then questions about the nature of the sociocultural activity from which such knowledge emerges are critical. Whose community, culture, history is the focus of the design activities (e.g., PartSim’s elevators, traffic gridlock)? What connections to students’ lives—lives that are situated in social, cultural, historical, political arenas—do design activities include? If the goal is design of generative activities, how do they facilitate students’ development of meaningful mathematics that can help them take action on their world? Linguistic and cultural diversity in classrooms push notions of participation, as well as historical notions of student and content. (O. Lee’s (1999, 2000) work in inquiry-based teaching is germane in science education.) What kinds of considerations need to be made in inviting the contributions of, for example, English as a second language learners as legitimate participants whose language and culturally grounded knowledge are viable, important resources for assessing proof (for example), and for teaching and learning?

Further, attention to the fundamental influences of culture and language on learning (similar to Kaput's work (Kaput & Shaffer, in press) on externalized manipulation of formal systems changing the very nature of cognitive activity) may make visible heretofore unexamined notions of appropriate interaction and participation in the new social spaces created within networked classroom environments.

And finally, relative to developing more culturally situated notions of participation, a somewhat uncritical focus seems to be on mathematics as a universal language. Treating language as a mediating tool through which structures emerge poses interesting challenges to universality. To explicate what is truly meant by claims that mathematics is constructed through sociocultural activity, the mutually constitutive relation between the language of mathematics and the structure of classroom activity, as well as between the language of the classroom and the structuring of mathematics, must be explicated more fully. In addition, in networked classrooms, the expansion of language through the production of new artifacts (e.g., real-time public displays of jointly constructed knowledge) and the nature of the conversations that have public construction and display as their focus offer unique glimpses into the development of mathematical knowledge and reasoning. They also have potential to invite diverse modes of communication and interaction into the process. Careful examination of the new avenues for socially and culturally specific communication and interaction can optimize the generative potential of the new social spaces created in networked classroom environments.

To be fair, while a critique of mathematics education as acultural, ahistorical, or apolitical is possible, critiques of sociocultural theoretical frameworks for ignoring content are also important in extending prior analyses, as we begin to do in this paper. Socioculturalists have helped researchers and educators focus on the reality of the social construction of mathematics, however, they have done less well in attending carefully to the dialectic proposed here because of a disconnection from content. There has been (with some exceptions, e.g., Gauvain's (1998) work on cognition being shaped over time by various number systems) one-way attention to the fundamental connections between activity and learning, looking more at activity structuring learning rather than also looking at domains structuring learning through activity. Thus, the dialectic framework proposed here has potential to enrich both sociocultural research and theory and mathematics education by bringing them into conversation with each other.

mkh2@psu.edu

Activity for this Discussion Group will center on framing ways to think about the role and nature of symbolic reasoning in secondary school and early college mathematics. Perspectives on this issue will be through presentations during the first session and through papers shared prior to the meeting. One possible goal for the group will be the production of a collection of more refined papers on issues such as the nature of and relationships among symbol sense, symbolic reasoning, symbolic manipulation, symbolic insight, and symbolic disposition.

The advent of CAS calculators in a growing number of schools, the international attention (Australia, Austria, France, England, etc.) being focused on CAS in schools, and the recent attention to CAS issues by the National Council of Teachers of Mathematics are factors that contribute to a growing need to develop a better understanding of the nature and role of by-hand and technology-assisted symbolic work. Past attention to symbolic work had focused on development of symbolizing in younger children (Cobb, Yackel, & McClain, 2000) and on beginning to define what might be meant by symbol sense (Arcavi, 1994; Keller, 1993/1994; Pimm, 1995). This symbolic reasoning discussion group is a follow-up on a very small invited conference on symbolic reasoning held several years ago in Bethany Beach, Delaware. The Bethany Conference focused on symbolic work at the high school and early college levels.

The Bethany Conference was assembled to consider the role and nature of symbol use in school and early college mathematics. Participants included mathematics and mathematics education faculty and doctoral students from Penn State, University of Iowa, University of Delaware, and Iowa State University. That conference generated questions and sought clarification on the issue of the nature of and relationships among the following: symbol sense, symbolic reasoning, symbolic manipulation, symbolic insight, and symbolic disposition. Questions that were raised include:

- What is the role of symbolic manipulation programs in the development of an ability to work with algebraic symbols? What new understandings of symbols will be required in a CAS-intensive mathematics classroom?
- What are the relationships between conceptual understanding and symbol sense, symbolic reasoning, symbolic manipulation, symbolic insight, and symbolic disposition?

- What is the impact of work with symbols on the disposition to verify mathematical claims symbolically?
- What is the impact of particular symbol systems on the development of symbol sense?
- To what extent can the development of symbol sense be informed by the metaphor of enculturation into a language?

### Some Thoughts on Key Questions

Understanding and use of algebraic symbols is a topic of prime importance in mathematics education, and one for which essential questions remain unanswered. In this section, we make some observations from extant research literature, point to issues raised in this literature, and raise some questions that may be important in furthering our understanding of work with symbols in mathematics. Our observations are organized around the aforementioned list of questions.

*What is the role of symbolic manipulation programs in the development of an ability to work with algebraic symbols? What new understandings of symbols will be required in a CAS-intensive mathematics classroom?*

Constructs pertinent to the role of symbolic manipulation programs include the white box/black box principle and how it may be used to think about the relationship of students' use of CAS to the didactic approach taken in the classroom (cf. Heugl, 1997). This immediately raises the question of how and to what extent by-hand symbolic manipulation contributes to students' understanding of symbols. One perspective on how this might be addressed is the issue of technique, as discussed by Lagrange (1999) and others.

*What are the relationships between conceptual understanding and symbol sense, symbolic reasoning, symbolic manipulation, symbolic insight, and symbolic disposition?*

Herscovics and Linchevski (1994) observed that students without formal instruction in algebra (as in symbolic manipulation) used strategies based on inverse operations to solve equations in one unknown. The students, however, abandoned manipulations of the equations and resorted to guess-and-test strategies when the equations involved two unknowns. Herscovics and Linchevski connected this work with prior work on the meaning of the equal sign. It seems to us however that this work also suggests that students' sense of a symbolic item is related to their use of symbolic manipulations.

Mason (1980) described the conjecturing process in mathematics in terms of three components. It begins with doing particular examples that one "can manipulate easily while part of [one's] attention remains focused on [one's] primary goal" (p. 10). One then possibly calls on diagrams or metaphors as one tries to get a sense of

the underlying pattern or relationship. Lastly, one continually articulates and refines the pattern. Mason's notion of starting with manageable examples seems to underlie the task structures suggested by Drijvers (in press). The structure of Drijvers' CAS classroom examples with systems of equations involves approximately two questions similar in structure but with different numbers. The last part of the task then moves beyond specific numbers and into the use of variables. This structure seems to parallel Mason's notion of starting with the more manageable and then changing focus to the underlying pattern. Classroom tasks such as these may capture the essence of Mason's point that students need supports that give meaning to symbolic forms. We also raise the question of to what extent the specific, manageable instances should be examples done by hand or by head, in the absence of CAS or other supporting technology.

An understanding of work with symbols requires understanding what it means to be fluent in the use of symbols, and such fluency would involve understanding the relationships among conceptual understanding, symbol sense, symbolic reasoning, symbolic manipulation, symbolic insight, and symbolic disposition. One way researchers have observed students' fluency with symbols is to study how students use symbols in the solution of non-routine problems. Two decades ago, Rosnick (1982) observed that participants in his study had an inclination to use algebraic symbols as labels for "broad, undifferentiated concepts." He remarked on their abilities to shift among different interpretations of a symbol within their work on a single task.

In her study of college calculus students' nonroutine problem solving, Kinzel (2000) added to the conversation about fluency with algebraic symbols when she characterized students' work with symbols in her study of the interpretation and use of algebraic notation by college calculus students. She observed several categories of factors that typified students' use and interpretation of symbols. First, she observed that a key factor in students' work with algebraic notation was the extent to which students attended to the definitions of the symbols with which they worked. For example, one of the participants in Kinzel's study shifted among interpretations of symbolic expressions; her loose definition of  $d$  allowed her to use  $d$  to represent "number of days" and simultaneously to use  $\frac{20}{d}$  as an abbreviation for  $\frac{20 \text{ miles}}{1 \text{ day}}$ . Kinzel pointed out that "Such conflict obscures the mathematical relationships between the quantities and thus compromises her [the student's] representation of those relationships." (p. 333). However, such loose attention to definition of symbols does not always compromise the mathematical meaning of the symbols, however, as one participant in Kinzel's study seemed to operate from a loose definition of symbols while maintaining an awareness of the verbal interpretation of the formula. Another of Kinzel's categories of factors centered on the influence of students' attention to symbolic manipulation. Although students may have paid careful attention to defining particular notation when they first introduced it, they lost sight of that meaning once they became involved in

symbolic manipulation and changed the meaning of the symbols to suit the manipulation. At times, students' intention to use particular symbolic manipulations influenced the form of their representations. To Kinzel, key to fluency with algebraic symbols was attending to and integrating the selection, manipulation, and interpretation of algebraic notation. We believe that the understanding of the nature of this balance is crucial to understanding the nature of symbolic work in school and college mathematics.

*What is the impact of work with symbols on the disposition to verify mathematical claims symbolically?*

Heid, Blume, Iseri, Flanagan, Kerr, and Marshall (1997) observed juniors and seniors in college as they solved non-routine problems. The researchers observed a tendency among three of the four target students to reason toward symbolic representations but not to reason from them. Seeming to view the production of a symbolic representation as a terminal goal, students resorted to the numerical or graphical forms as representations from which to reason.

In summarizing the role of visualization in doing mathematics, Noss, Healy and Hoyles (1997) drew on Hadamard (1945) for evidence of the absence of typical symbols in mathematicians' initial work with problems. Healy's group noted the importance of the mathematicians' skill in moving between the formal symbolic work and more informal modes of thinking. Healy and colleagues paired observations of mathematicians with the findings of Hillel, Kieran, and Gurtner (1989). The resulting stance contended that students prefer not to draw on mathematical knowledge when they can reason by perceptions when diagrams are present. Healy and colleagues raised the question of what happens when microworlds are used. We would tend to ask the related question, how might computer algebra systems and other computer environments be used to challenge students' non-symbolic tendencies while still respecting the potential for non-symbolic work in the initial stages of problem solving and of learning mathematics.

*To what extent can the development of symbol sense be informed by the metaphor of enculturation into a language?*

If mathematics is a language, the symbols used may be the written word. We not only raise the question of how individuals construct and interpret mathematical symbols but we also ask to what extent this question may be informed by drawing on research and theory in reading and foreign language education. Constructs in these fields such as encoding and decoding capture the change of thoughts into written forms and conversely from written word into thought. There seem to be parallels to these in work with mathematical symbols. For example, Kirshner (1989) concluded students depended on cues in the surface features (e.g., spacing between individual symbols) of ordinary notation in order to evaluate algebraic expressions. Ericksen (1991) noted that students saw more surface-level features but struggled to recognize deep patterns

in algebraic expressions, sentences and sequences. She raised questions about how what is obvious to the mathematically experienced is not obvious to the learner. Erickson also questioned the role of conceptual understanding in seeing structures. English and Sharry (1996) also questioned how students become able to identify relationships and to unpack symbolic expressions. In making the connection with the language metaphor, we ask questions about the extent to which research on individuals' comprehensive of Chinese symbols for native and second-language speakers may inform how learners and more mathematically experienced individuals perceive and give meaning to strands of mathematical symbols.

### The Work of the Discussion Group

This PME-NA Discussion Group seeks to expand the conversation about symbolic work to a larger pool of researchers and to develop collaborative papers addressing the concepts of symbol sense, symbolic reasoning, symbolic manipulation, symbolic insight, and symbolic disposition. Our goal would be the collaborative production of a series of papers for consideration as a special issue of the *International Journal on Computer Algebra in Mathematics Education* (IJCAME).

Invited short talks will be used as a vehicle to begin the conversation, addressing issues related to the following: symbol sense, symbolic reasoning, symbolic manipulation, symbolic insight, and symbolic disposition. In addition to the invited talks, Discussion-Group participants may submit additional papers addressing issues related to the work of this discussion group to post on a web site. To obtain the URL for the web site, participants should contact M. Kathleen Heid at mkh2@psu.edu. Papers should be sent to rmz101@psu.edu. An initial goal of the discussion group is to define topics and provide possible frameworks for potential papers and to form groups of researchers who could meet and work in the intervening year. Subgroups may communicate electronically and meet at the Annual NCTM Meeting, at the AMS-MAA Joint Meetings, at the annual AERA meeting, and/or at the MAA MathFest, so that drafts of papers on the topic could be ready for critique by the group at the 2003 PME-NA meeting. As drafts are posted, a list-serve will be created for this group and discussion of the papers would be ongoing. Those drafts would be revised during the 2003-4 academic year and would be prepared for submission to IJCAME soon thereafter.

# **Advanced Mathematical Thinking**

# **SOME CHARACTERISTICS OF MENTAL REPRESENTATIONS OF EXPONENTIAL FUNCTIONS – A CASE STUDY WITH PROSPECTIVE TEACHERS**

Peter Berger  
University of Duisburg  
berger@math.uni-duisburg.de

Günter Törner  
University of Duisburg  
toerner@math.uni-duisburg.de

Starting point is the hypothesis that spontaneous retrieval of knowledge graphs (= concept maps) entails relevant information on the organization, abstractness and the accessibility of mental representations of mathematical objects and allows conclusions on the structure of human long-term memory. In the following case study knowledge graphs on exponential functions from prospective teachers in their third academic year were spontaneously created and recorded, then concluded with interviews in which predominantly the steps of creating the graphic representations were retrieved. Comparison of the concept maps with the interview data revealed structures of the generation process of the knowledge maps, pointing to the meaning creation process of the original mathematical terms.

## **Objectives and Theoretical Framework**

The fact that for the past 10 years – declared by the Congress of the United States as the ‘Decade of the Brain’ – cognitive science has been ‘beginning to understand how the brain works and how it gives rise to the mind’ (Kosslyn & Koenig, 1995) is not least due to the contributions that the rapidly developing discipline of cognitive neuroscience has been making to this field. As the central concern of didactics is describing, understanding and influencing cognitive processes, we believe that theoretical cognitive research (Sigel, 1999), also in the framework of mathematics didactics, cannot ignore the ‘neuronal dimension’. As this ‘hardware level’ is not accessible for classroom research, we believe that at least the ‘software level’ should be given more attention. This central research dimension entails, amongst other aspects, the question of the *mental representation* of mathematical contents (Davis, 1987).

Our starting point, which brings mental representations immediately into play, is the basic hypothesis that the data collected in our observations entail more or less clear traces of active independent mental constructs from the long-time memory of our research subjects (prospective teachers). If learning is linked to mental rearrangement processes, then we can assume that a ‘new order’ is based on subjective consistent logic at least partially shaped or even controlled by these learning processes. Of course, autonomous processes may also have influenced rearrangement results. Our research interest focuses on these autonomous processes. Which retrieval processes are initiated under spontaneous access appears to us to be an open research question.

The number of contributions in mathematics education on mental representations has reached a two-figured number, but a uniform definition for mental representations

is not in view. After all, context-dependent (see Ball & Bass, 2000) as well as subjective experiences within and outside of mathematics (science, technology, everyday life etc.), which constitute the basis for mental representations, increase the difficulties in striving for a uniform approach. In the last instance individual research questions determine the favored model. Whereas Confrey (1991) views representations more as microstructures, we are more interested in the macrostructure aspect (cf. Pines, 1985). In agreement to this last approach we attempt to understand mental representations of mathematical knowledge as 'network structures' (directed or non-directed graphs) of knowledge that individually guide human information processing (Hasemann & Mansfield, 1995; Williams, 1998).

Thus, our data gathering process focuses on what may be described in terms of graph nodes together with vertices producing relations between these nodes. We thereby adopt the tool of concept maps developed by Novak & Gowin (1984) (also known in the literature as conceptual graphs), whereby we linguistically prefer the term 'knowledge graphs' (Zwanefeld, 2000). Novak & Gowin wanted to have an external representation of the way people store information in their minds. In the present study, a knowledge graph is viewed as a structured representation of acquired and (by the investigation) retrieved mathematical knowledge and skills. In the German academic world similar graphic representations (however with more limiting directives) are described as 'mind maps'.

It is clear to us that the structures described here as mental representations are scientific constructs, i.e. models with certain inherent basic assumptions. A description can furthermore only be undertaken indirectly, as we conclude the original representation from the information reproduction. It would be of great interest here to gain data from nuclear magnetic resonance tomography. The quality criteria for our approach are *adequacy* and *viability* of the chosen model, which subsequently justifies the approach or rejects it as unsuitable.

We will, however, extend this static 'two-dimensional' graph structure by a dynamic 'third dimension', namely time. Just as informative as the structure of the graph (the mind map) appears to us the process of its (re-)production in the interview context (when creating the mind map). Indeed our observations point to the assumption that the elements of an individual graph (a person's mind map) belong to different (background-) levels, and that these come into the foreground step by step, i.e. enter the consciousness level of the individual (generic aspect). It is hereby interesting to note whether, and if so, which patterns recognizably appear in these processes.

The chosen theme of *exponential functions* appears to us to be particularly suitable, and even to be of a high degree of relational content for this purpose, and to be an 'ideal critical research site' (Törner, 2001). If we understand the term *exponential function* as the 'conceptual root' of the mind map – as an 'evocational starting point' initiating an individual (re-)production process of a complex knowledge-network –,

then this reproduction stemming from the various nodes and vertices – so our hypothesis – follows certain ‘priority rules’. Such rules have already been postulated by Green (1971) in relation to beliefs, where he discusses the functional-generative categories ‘*primary versus derivative*’ beliefs as well as the ego involvement categories ‘*central versus peripheral*’ beliefs.

Our research objectives within the context of mathematical knowledge can thus be summarized into the following research questions: *What are observable representations? What are patterns of representation* on the background of the reproduction (retrieval) processes? How is then human long-term memory retrieved? It hereby remains an open question insofar this retrieval process is controlled by an object-independent retrieval program, or already contains context-dependent information packages which are unpacked when spontaneously activated (comparable to the memory of a zip file). Through our observation window the arguments seem to point more to the first alternative. The contributions from Sigel (1999) are partially devoted to related questions; only one contribution, however, is specific to mathematics (Lesh, 1999).

### Methods of Inquiry – Data Sources

Our data sampling integrates two corresponding data sources from voluntary test persons: *knowledge graphs* and *open interviews* (45–60 minutes, video-taped) on the theme of exponential functions. The survey was undertaken in 2001. Both authors jointly – in the form of a mutual ‘peer debriefing’ – did the work of data collection and evaluation. The interview partners were prospective teachers (upper secondary grades) in their third university year, so that one can principally assume they possess sufficient familiarity with exponential functions. We would like to point out that that in Germany it is obligatory for a prospective teacher to study two school subjects at the same level and scope. We will call the 6 students (2. academic discipline in brackets) Andrew (social sciences), Berta (chemistry), Chris (chemistry), David (physics), Ed (physics) and Fred (history).

An open interview style was chosen and carefully designed to avoid the impression of an examination situation. The interview participants were familiar with the concept-mapping method. We presented them for a short time a graphic representation of the Pythagoras theorem. We deliberately did not inform them of the theme of this survey beforehand. After revealing this theme to the students, they then had 10 minutes time to produce (unobserved) a knowledge graph on our theme in question (cf. appendix). As we were concerned with the macro-structuring of this subject matter, we deliberately did not give the candidates ample time to produce their knowledge graphs. We wanted to ensure that each candidate would be able to reconstruct the steps of the knowledge graph generation in the subsequent interview. Moreover, the produced graphic representations would have become too complex and thus their spontaneous quality would have been suppressed.

Following this, in the videotaped interviews the students were questioned in detail on the creation of their knowledge graphs (cf. the numbering of the nodes in the concept maps). We specifically questioned the students about the aspects: definition and application of exponential functions, their relations to logarithm functions, and their graphic representations – had they not commented on these aspects themselves.

### **Results**

The results presented here focus on the discussion of the graphic representations as a data source; we only marginally refer to the detailed transcriptions of the interviews. It would go beyond the scope of this paper to discuss the complementary, however not contrary, interview results here. We agreed in future to relate the name of the student to the name of the graphic representation produced by that person, as long as this does not lead to any misunderstandings. The mind maps of the six interviewees possess quite a broad spectrum of content richness and structural complexity standing in a certain correlation to the other subjects being studied by the individual students for their teacher degrees. The spectrum reaches from elaborated mind maps (chemistry [Berta], physics [Chris], [Davis]) across reasonably elaborated ones (physics [Ed], social science [Andrew]) down to less elaborated ones (history [Fred]).

As we are interested in spontaneous retrieval processes, we assumed that the global ‘locating’ of the initially unknown theme is of central relevance.

#### **The Affective Dimension**

Immediately after presenting the theme to the students we asked them how they would affectively categorize the theme: Andrew = rather rejective, Berta = positively loaded, Chris = neutral, Davis = neutral, Ed = “feel insecure“ und Fred = neutral, “not very secure”. It is surprising how reserved the many different facets this central theme in the academic curriculum are expressed. In particular the students Andrew and Fred, who both cannot relate this theme to their second academic discipline, reacted more rejectively than not.

#### **The ‘home-localization’ of the Theme**

The spontaneous subject-specific localization of the theme plays a key role, as the following knowledge maps demonstrate. We have to assume that relating a theme to mental information fields activates different retrieval processes. Illuminating was the short question asked in response to our question in the interview of Berta: “May I also use physics examples?” Sources of subjective localization are rather implicit information from the maps as well as verbal statements (e.g., quotations) from the interview. The following table lists these data.

| home...        | Andrew                        | Berta  | Chris                                | David   | Ed                             | Fred                                    |
|----------------|-------------------------------|--|--------------------------------------|---------|--------------------------------|---|
| map            | mathe-<br>matics,<br>calculus | mathe-<br>matics,<br>functional<br>equations | processes<br>of growth<br>in physics | physics | mathe-<br>matics,<br>functions | Mathe-<br>matics,<br>Eulerian<br>number |
| inter-<br>view | mathe-<br>matics              | coaching<br>maths stu-<br>dents              | everywhere<br>in physics             | physics | mathe-<br>matics               | mathe-<br>matics                        |

When we speak of home localization we implicitly define in a dual mode a so-called outer location which is not necessarily explicitly mentioned but is nonetheless exactly for this reason present; Fred for example does not like to address aspects from physics: "I am absolutely not very good at physics!". The inner-outer view (Green employs the terms central and peripheral) underlines the relevance of the home localization, which could be confirmed by the interview statements.

### Around the Mathematical World

It has been noted by a number of authors that beyond the dynamics of the conceptual network of mathematics there is a world of stabilized expectations and beliefs which deeply influence the reception as well the use of mathematical and scientific knowledge (see e.g., Fishbein, 1987). Thus it is fundamental to identify these intuitive forces and to take them into account in analyzing the pattern of the retrieval process. The mathematical worldview of a physics-oriented student will perceive mathematics in a trivial fashion differently than a "pure" mathematician. In particular, mathematical schemata and systematics such as definition, theorem and lemma appear to fade away.

### The Pattern of Retrieval

The present six knowledge graphs point to a few retrieval heuristics, which are nonetheless explainable. Basically, when drawing a graph one is generating another node, thus one is probing in a suitable direction towards a new aspect. One of the fundamental principles is the 'variation of a constant' - to employ a mathematical principle as a metaphor. A number of approaches appear to be obvious here: First of all there are the completely mathematically neutral classical variation principles: from the *specific to the general* (David) as well as from the *general to the specific*. (Ed). Here switching backwards and forwards between the exponential functions (logarithm function) with a random basis  $a$  and the classical exponential functions (natural logarithm function) occurs. Alongside these heuristics one can also list variations on the linguistic level when searching for suitable associations (cf. Fred): Here the theme exponential function is also varied over the letter  $e$ , synonymous for the Eulerian

number. One has the impression of a rather helpless non-directed search. Fred does not leave his mathematics home location; a fruitful link to his parallel academic discipline history cannot occur for content reasons.

More successful, as it is more mathematics-specific, is the *variation on the linguistic level*. Here term representations undergo variations, and formula representations are manipulated. The *variation on the conceptual level* can be viewed as a further development of the aforementioned principle; here we are dealing with associations that can also be understood as dualisms: term representation, graph representation, function, inverse function. Our interviewees represented their knowledge contents – at least in the context of the exponential function – often very clearly in the form of dualisms (graph - term, function - inverse function, application - theory, figurative - formal, approximately - precise, reality - school, learn - forget, know it - look it up). Notably, even dualisms that are in fact symmetric (and when asked, the interviewees are aware of this symmetry) are nonetheless represented as a rule in a hierarchical form. Thus logarithm functions are conceptualized as inverse functions of exponential functions, but not vice-versa. The opposite direction is felt to be ‘unnatural’: logarithm functions, perceived as ‘complicated’, are ‘reconstructed’ from the simpler concept of exponential function by inversion. Other dualisms also appear to be conceptualized as dichotomies with inherent assessment in the forms: ‘simple-difficult’, ‘important-unimportant’, ‘good-bad’ or similar. We tend to interpret these observations in such a manner that representation (even) of mathematical knowledge is ‘emotionally charged’ (cf. central versus peripheral mathematical beliefs).

### **Dominance of context-relevant aspects**

(Aspect: anti-didactic, objective-logical nature of mathematics.)

Characteristic for the (mathematical!) definition of the exponential function is that it fulfills the differential equation  $f' = f$ . The identity of  $f$  to its differentiation is insofar constitutive and unique for this function. It is surprising that this central differentiation aspect in the mind maps is allocated only secondary priority - a tendency more or less strongly supported in the interviews. The same can be said about the interviews, in which conscious mentioning of the  $f' = f$ -property (if at all) occurs at a very late stage. We explain this fact by noting that the systematics of a function discussion mentions the  $f' = f$ -property later, and this consequently influences the retrieval process. The logical nature of mathematics has insofar an anti-didactic effect here.

### **Door-opener resp. dead end**

We would just like to shortly mention this aspect. Individual nodes of the graphs point to a high networking index, which strikes one’s attention immediately. They are equally starting points for (interdisciplinary) associations in various directions, for example the aspect of exponential growth links to physics (see Andrew, Chris, David, Ed), to economics (see Andrew, Berta), to chemistry (see Berta), to geography (see

Chris) and to biology (see Chris). On the other hand there appear to be nodes that can be called 'dead ends', when for example Fred reflects the theme domain under the didactic aspect of how to teach it in schools.

### **Aspect: Piggyback**

Sigel (1999) throws up the question: 'Does emotion involve a separate representational system or does piggyback affect onto other systems?' We believe in the productive nature of this piggyback aspect: Our interviews reveal numerous instances of colorful emotionally affected details.

### **Conclusions**

It is apparent to our authors that the observations made here cannot be uncritically generalized without limitations. On the other hand they agree to preceding implicit observations and feature patterns of generalized structures. We consider home localization, which occurs quite spontaneously, to be of decisive importance. The home domain functions as a reference level to which the interviewee always finds his way back, and which also controls retrieval processes to a great extent. In the case of the interviewees, those students akin only to mathematics presented only limited knowledge maps, whereas those students who were science oriented presented more multifaceted aspects. The networking of science contents with mathematical contents and viewpoints, however, had its deficiencies. We have to assume that interdisciplinary linking of content is not automatically executed by the learner but has to be explicitly taught. Moreover, home localization determines the sense-making of mathematical objects and terms (differentiation, growth etc.). It seems as if the university course for mathematics does not take this aspect sufficiently into consideration. Spontaneous reporting of memorized information from the long-term memory does not seem to be determined by the primarily requested content, as if one were to expand a stuffit file. On the contrary: 'home'-specific routines seem to considerably influence retrieval. Home localization of a theme is insofar a key factor; decisive for home localization is in particular the domain that guarantees sense-making of the mathematical object.

Our observations reveal that the classical way of imparting mathematical knowledge (lectures) does not guarantee the emergence (or construction) of a relevant and sense-making 'mental network of mathematical knowledge' in our students – at least in the context of exponential functions. It seems that natural science subjects (chemistry, physics) are allocated specific functionalities here that (regretfully) cannot be mediated solely within mathematics studies. The effects of other subjects upon mathematical knowledge that we observed (a neglected aspect in research) appear to be a rather ambivalent but nonetheless relevant phenomenon for the development of mental representations of mathematical knowledge, which we would like to investigate in further going studies.

From a methodological point of view our survey has demonstrated that research into mind maps only allows correct analyses if in the research context also the production process of each map is illuminated, for instance by a subsequent interview. The mere graph structure of a mind map often leads to improper results, as 'nearness on the paper' may conceal the actual (chronological) distance of mind map elements. While the static graph structure essentially depicts the 'stored representation' of knowledge, the interview offers insight into the dynamics of the 'working memory'.

## THE OPERATION TABLE AS METAPHOR IN LEARNING ABSTRACT ALGEBRA

Bradford R. Findell  
University of Georgia  
bfindell@coe.uga.edu

This paper presents an analysis of the ways that one particular student used operation tables to support her reasoning about groups, subgroups, binary operations, and their properties. Based on interviews in the context of an undergraduate course in abstract algebra, the student's reasoning processes were external and based in the operation table, so that in large measure the operation table *was* the group for this student and, to a lesser extent, for other students as well. This result provides insight into the role of multiple representations in supporting the emergence of abstract mathematical objects in students' thinking.

### Introduction

Among the growing research literature in undergraduate mathematics education, there is comparatively little attention to the learning of abstract algebra. This paper presents selected results from a dissertation (Findell, 2001) on learning and understanding in abstract algebra. To complement to the extant literature describing action, process, and object conceptions of topics in elementary group theory (e.g., Asiala, Dubinsky, Mathews, Morics, & Oktac, 1997; Brown, DeVries, Dubinsky, & Thomas, 1997; Dubinsky, Dautermann, Leron, & Zazkis, 1994; and related literature describing difficulties with particular concepts in group theory (Hannah, 2000; Hazzan & Leron, 1996; Leron, Hazzan, & Zazkis, 1995; Zazkis, Dubinsky, & Dautermann, 1996; Zazkis & Dubinsky, 1996), the study sought to identify prominent features and components of students' concept images (Tall & Vinner, 1981) in the context of an undergraduate course in abstract algebra.

Analysis of interviews and written work from five students provided insight into their concept images of topics in elementary group theory, revealing ways they understood the concepts. In attempting to describe and explain the data, well-known theoretical constructs seemed insufficient. Thus, analysis became a process of theory generation, and much of the conceptual and analytic framework emerged during the analysis through use of the constant comparative method (Cobb & Bauersfeld, 1995; Glaser, 1992; Glaser & Strauss, 1967). Because many salient episodes in the data involved seemingly idiosyncratic uses of language and notation, the analysis was essentially semiotic, using the students' linguistic, notational, and representational distinctions to infer the students' conceptual understandings and the distinctions they were and were not making among concepts. The perspective on semiotics was based in the work of Peirce (1955) as well as recent contributions by Sfard (2000) and others (e.g., Cobb, Gravemeijer, Yackel, McClain, & Whitenack, 1997; Gravemeijer, Cobb,

Bowers, & Whitenack, 2000; Pimm, 1995). The framework also took advantage of the distinction between process and object conceptions (e.g., Dubinsky, 1991; Sfard & Linchevski, 1994) as well as various perspectives on abstraction and generalization (Dienes, 1961; Frorer, Hazzan, & Manes, 1997; Hazzan, 1999; Wilensky, 1991) and the metaphorical nature of mathematical thinking (Lakoff & Núñez, 1997, 2000). As the conceptual and analytical framework emerged, the data were synthesized under two themes: making distinctions and managing abstraction. This paper discusses the latter theme, focusing in particular on the ways that students used operation tables to manage abstraction.

### Analysis

This research report concentrates on one student, Wendy, whose reasoning was particularly tied to operation tables. All interview excerpts are taken from the first of four interviews with Wendy. The guiding question for this interview was, “Is  $Z_3$  a subgroup of  $Z_6$ ?” (see Hazzan & Leron, 1996). Before presenting data and analysis, I discuss Wendy’s use of language, which bears on the interpretation of the data presented.

Wendy often misused words, saying one word while meaning another, such as multiplication for addition, identity for inverse, or associativity for commutativity. Sometimes she corrected herself immediately, other times she corrected herself when I asked for clarification, and occasionally her linguistic missteps suggested deeper conceptual difficulties. In any case, such slips-of-the-tongue were shown to indicate strong connections among the concepts that the words represented (see Findell, 2001). Because slips-of-the-tongue are not a focus of this paper, I use brackets in the transcripts to indicate the word that she likely meant.

#### *What is the operation in $Z_6$ ?*

As Wendy began the interview, she was uncertain of the meaning of  $Z_6$  but surmised that it was “integers mod 6” (line 11). She wanted to create “a total table” (line 13) and then realized that she would need to determine the operation. She discussed both addition and multiplication as possibilities and began constructing a table for multiplication in  $Z_6$  (see Figure 1).

Wendy: Okay. Well,  $Z_6$  is not going to be, when I start with my chart, and I do the first row, 0 times any element is going to equal 0, so if you look at that.... Actually, okay. Let me just.... It’s not going to have.... You have to.... I’ll just finish it [the row]. Okay, now it has to hold four properties to be a group. Let’s write these down. It has to have an identity, an inverse, it has to be closed, and it has to be associative, which we’re going to leave for last. [Laughs] (line 20)

Wendy: If you look at this row [the “1 row”], you multiply.... If I.... I am calling 1 the identity. If you multiply 1 by every element, you get the element back,

get the original element back. So, like 1 multiplied by this row gives you the same row back. (line 26)

Wendy's inclination to finish rows and to write down names of the group axioms suggests that she preferred to have visual supports for her reasoning. She reasoned about both the action of the 0 and 1 on individual elements and the action of the identity on an entire row of the table. As she constructed the next row in the table, she considered the inverse property.

Wendy: So if you look at the second row [the "2 row"], there is no number when you multiply.... If you take  $m$  equaling 2, if you take a number equaling 2, when you multiply, there is nothing to multiply by 2 to get—in mod 6, cause it has to be an element, to be closed, you can only work with the elements within mod 6. And I have tried every element, 0, 1 ... 0 through 5, multiplied by 2 to see if I can get the identity, 1, and I can't get it. So therefore,  $Z_6$  is not a group under multiplication. (line 34)

| $\times$ | 0 | 1 | 2 | 3 | 4 | 5 |
|----------|---|---|---|---|---|---|
| 0        | 0 | 0 | 0 | 0 | 0 | 0 |
| 1        | 0 | 1 | 2 | 3 | 4 | 5 |
| 2        | 0 | 2 | 4 | 0 | 2 | 4 |
| 3        | 0 | 3 |   |   |   |   |
| 4        | 0 | 4 |   |   |   |   |
| 5        | 0 | 5 |   |   |   |   |

| $+$ | 0 | 1 | 2 | 3 | 4 | 5 |
|-----|---|---|---|---|---|---|
| 0   | 0 | 1 | 2 | 3 | 4 | 5 |
| 1   | 1 | 2 | 3 | 4 | 5 | 0 |
| 2   | 2 | 3 | 4 | 5 | 0 | 1 |
| 3   | 3 | 4 | 5 | 0 | 1 | 2 |
| 4   | 4 | 5 | 0 | 1 | 2 | 3 |
| 5   | 5 | 0 | 1 | 2 | 3 | 4 |

Figure 1. Wendy's tables for addition and multiplication in  $Z_6$ .

Thus, Wendy had developed a procedure that could be used in verifying the inverse property. To find the inverse of any element in a set, she multiplied that element by every element of the set to see whether the result was ever the identity. Although the operation table may be considered as merely providing an organizational scheme for the necessary calculations, Wendy's procedure was based "in the table" in the sense that she preferred the whole row to be present. In fact, she used this procedure to reconsider the "0 row":

Wendy: Actually, up here, in multiplication, I didn't even have to look at the second row [the "2" row] because if you look at 0 there is nothing you can multiply by 0 to get the identity element back, 1, because 0 times every element is going to equal 0. (line 38)

Having abandoned multiplication modulo 6 as the operation in  $Z_6$ , Wendy began constructing a table for addition in  $Z_6$  (see Figure 1) and quickly stated, "I can see by filling out the first table [row] that the identity" is zero (line 47), suggesting that her

recognition of the identity was tied more strongly to visual aspects of the table than to mental reasoning about the operation. She went on to consider the other group axioms.

Wendy: So next I am going to check the inverse property. And 0 has an inverse so  $0 + 1$ , or.... Excuse me. Since 0 is the identity we have to check that when you add 0 to 0 you get the identity 0. So 0 is the inverse element for itself. And then 1. When you multiply, when you add 1 and 5 it equals 6, but that equals 0 (mod 6) cause 6 is divisible by 6. That's pretty obvious, but.... So 1 has a inverse. 2 has an inverse because  $2 + 4 = 6$ , which equals 0.  $3 + 3$  has an in-.... equals 0 (mod 6).  $4 + 2 = 0$  (mod 6). And  $5 + 1 = 0$  (mod 6). So each element has an inverse. So you know that  $Z_6$  is a group under addition.

Wendy: And then it's closed. You can see that there are no elements other than 0 through 5, looking at the chart, because we have all possible combinations on elements in  $Z_6$ . So it is closed also.

Wendy: And associative. You can see, because the chart has symmetry, that the group will be, is associative. This is how I look at it, anyway, because if you look at  $2 \times 5$  you are going to get 1 and if you look at  $2 + 5$  you get 1. (lines 50-52)

Wendy correctly verified the inverse property by using the table to find the inverse of each element. She supported this process by making a check mark alongside each row of the table as she identified the corresponding inverse. In verifying the closure and associative properties, Wendy explicitly referred to the table to support her reasoning, but she made several errors in her attempt to verify associativity. First she stated that she was comparing  $2 + 5$  and  $2 \times 5$  when, based on her statement about the symmetry in the table, she probably was comparing  $2 + 5$  and  $5 + 2$ . A more significant error was that she was describing commutativity but calling it associativity. Finally, the penultimate sentence implies that she thought that  $Z_6$  is a subgroup of  $Z$ . During the interview, I pursued and she quickly corrected the first two errors.

### Observations

Although the students had been working with the groups  $Z_n$ , all of the students who were interviewed expressed some uncertainty about the operation in  $Z_6$ , and most of these students used operation tables to support their reasoning. To verify the group axioms, Wendy had created procedures based in the operation table. Her reasoning was largely external, however, in that it seemed to require the presence of the table. Other students developed similar procedures, but none were as tied to the table as Wendy.

The above excerpts provide some explanation for the fact that Wendy sometimes confused the words and syntax while discussing the group axioms and related prop-

erties. The identity and inverse properties were closely related in Wendy's thinking partially because finding an inverse for an element involves looking for the identity in a particular row or column of the table. Similarly, when using an operation table, commutativity is more salient than associativity, leading to misstatements by Wendy as well as other students. Noting the symmetry in an operation table, they claimed that the operation was associative when the symmetry indicated instead that the operation was commutative. Thus, although an operation table supports students' reasoning, it may also contribute to conceptual and linguistic difficulties.

### *Is $Z_3$ a subgroup of $Z_6$ ?*

After determining the operation in  $Z_6$ , Wendy was able to take on the question that had been posed at the beginning of the interview.

Wendy: Now is  $Z_3$  a subgroup of  $Z_6$ ? Now, we have to check that  $Z_3$  is going to be a group because it has to have all of the elements [axioms] of a group, which means it has to have identity and inverse; it has to be closed. So I am going to start checking  $Z_3$ .  $Z_3$  would consist of 0, 1, and 2 under addition. But  $Z_3$ , the table is going to be different. See I am going to have to explore right now whether or not.... When you say  $Z_3$  is a subgroup of  $Z_6$ , whether it means you are taking  $Z_3$  out of  $Z_6$ , or if you are just looking at  $Z_6$  [ $Z_3$ ] and seeing whether it's a group. See when you say something is a subgroup of something else [pause] I am not quite sure what way to look at it. Like how it exactly, like how  $Z_3$  ties into  $Z_6$ , like to be a subgroup of  $Z_6$ . What, that.... Like I know how to check whether or not  $Z_3$  itself is a group and whether  $Z_6$  is a group, but to check whether  $Z_6$ ,  $Z_3$  is a subgroup of  $Z_6$ , I don't know exactly what to look at. (line 76)

Wendy had a sense that the operation table for  $Z_3$  would be different, depending upon whether it was constructed on its own or taken out of the operation table she had just constructed for  $Z_6$ . Consistent with the hypothesis that Wendy's reasoning was highly dependent on *looking* at an operation table, her statement "I don't know exactly what to look at" suggests she didn't know what *table* to look at.

The literature on the learning of group theory indicates that although students think of a group as a set, they are not always sufficiently aware of the operation (Dubinsky et al., 1994). For Wendy, however, the operation remained prominent because of her reliance on the operation table, which suggests a much stronger observation than has been made thus far. Rather than saying the operation in  $Z_3$  is different, Wendy said, "But  $Z_3$ , the table is going to be different," implying that the table was not merely supporting her reasoning but rather was substituting for the group in her thinking. The phrase "taking  $Z_3$  out of  $Z_6$ " implies again that, for Wendy,  $Z_6$  was not merely a list of elements that appeared on the edges of the table but was in fact the table. This observation is further supported by the following excerpt in which Wendy referred not to the group  $Z_6$  but again to the table:

Wendy: Because if you use the elements of  $Z_3$ , which is 0, 1, and 2—are the elements of  $Z_3$ . But if you look at them in terms of  $Z_6$ , like if you just look at this section of the table  $Z_6$  [dotted square in Figure 2], this isn't going to be a group.... Because it is not closed.... Because 4 isn't an element of  $Z_3$ . (lines 78-82)

Thus, through her reliance on the table, Wendy had correctly identified the central issue behind the interview question: whether the addition was to take place based on the operation in  $Z_3$  or in  $Z_6$ . Nonetheless, she was not ready to come to a conclusion.

Wendy: See, it doesn't make sense. Like, I started over here to do, to look at whether or not  $Z_3$  was a group itself, but that didn't make sense to me ... [t]o look independently to see whether  $Z_3$  was a group under addition. (lines 86-88)

Wendy was bothered by a contradiction that was implicit in the interview question.  $Z_3$  and  $Z_6$  are each groups if they are considered separately, but the concept of subgroup prohibits such separate consideration. Her thinking coalesced later in the interview:

Wendy: I think we have to look at it  $Z_3$  as like part of the set of  $Z_6$ , which, like subgroup, like as a group in  $Z_6$ . So if you look at ... which is why I kind of choose the elements  $Z_3$  out of the  $Z_6$  table. (line 111)

Wendy was clearly thinking of  $Z_6$  as more than a set and of  $Z_3$  as more than a subset. She was choosing entries out of the  $Z_6$  table that corresponded to the restriction of the binary operation to the subset  $Z_3$ . On the conviction that this was the appropriate method for thinking about a subgroup, Wendy decided that  $Z_3$  is not a subgroup of  $Z_6$  because the subset was not closed under the operation.

### *Are there subgroups of $Z_6$ ?*

The fact that Wendy had answered the interview question was apparently of little concern, for she immediately began looking for subsets of  $Z_6$  that could be subgroups. In particular, she considered the set  $\{3, 4\}$  and saw from the table that 4 wouldn't have an inverse. She generalized the question "Is  $Z_3$  a subgroup of  $Z_6$ ?" to consider whether  $Z_n$  might be a subgroup of  $Z_6$  for other  $n$ , but saw that the closure property wouldn't be satisfied.

I asked explicitly whether she could find a subset that was a subgroup.

Wendy: See  $Z_6$ , it's hard to take a subset because you have to make sure you include the identity

| + | 0 | 1 | 2 | 3 | 4 | 5 |
|---|---|---|---|---|---|---|
| 0 | 0 | 1 | 2 | 3 | 4 | 5 |
| 1 | 1 | 2 | 3 | 4 | 5 | 0 |
| 2 | 2 | 3 | 4 | 5 | 0 | 1 |
| 3 | 3 | 4 | 5 | 0 | 1 | 2 |
| 4 | 4 | 5 | 0 | 1 | 2 | 3 |
| 5 | 5 | 0 | 1 | 2 | 3 | 4 |

Figure 2. Wendy's table for  $Z_6$ , annotated version. [Circles added to clarify transcript]

element in the set that you pick. So let's, just for instance, I'm going to take this. Because if I am looking in the fact that you have to have an identity element. Here, if you look at 1, 2, and 3 they each have and 3, 4.... You can't do that. 'Cause now it's not closed, really. You can't take 3, 4, 5 and 1, 2, 3. It wouldn't work. (line 144)

Wendy saw that she needed to include the identity, but she was simultaneously considering "blocks" in the operation table, and she saw that this would not work. After I suggested that she consider nonadjacent elements, such as 3 and 5, I noticed that she was covering up the 4 in the table. She explained:

Wendy: It distracts me. Technically you are only looking at the 0, 2 ... 2, 4 [circled in Figure 2]. Right? Because, in other words, you can make that table.... You can't look at the other elements. You can't look at the whole row, 3 and 5. You know what I mean? Because you can only look at the addition of those two. (line 150)

Wendy indicated how she was restricting her view of the table, listing precisely those entries inside the table (0, 2; 2, 4) that are relevant to whether  $\{3, 5\}$  is a subgroup. Furthermore, she justified this view by noting that "you can make that a table." From this view, she noticed that 5 does not have an inverse in  $\{3, 5\}$  because "when you add 3 or 5 to 5, you can't get 0" (line 152).

Wendy next decided to begin with the set  $\{1, 5\}$  to see whether it is a subgroup of  $Z_6$  because "if you took those two separately, it upholds the inverse property" (line 162). Realizing that she also needed an identity element, she then considered the three-element subset  $\{0, 1, 5\}$ . She chose to "move this over" (line 166) to create a new uncluttered table (see Figure 3).

After completing the table for  $\{0, 1, 5\}$  and verifying the identity and inverse properties, Wendy noticed, with some frustration, that "It's not closed. [Laughs.] Oh, no. It's got 2 and 4 in it. This is just getting really difficult" (line 173).

With the failure of the closure property, Wendy focused on closure and realized that any subgroup that contains 1 must also contain 2, then 3, 4, and 5. I asked her what would happen if she started with something else.

Wendy: If you start with 2 you are going to need 0. You are always going to need 0, 'cause, like you said. Okay. So, things are getting kind of messy. I need a new piece of paper. If you start with 2, you're going to need 4.

| + | 0 | 1 | 5 |
|---|---|---|---|
| 0 | 0 | 1 | 5 |
| 1 | 1 | 2 | 0 |
| 5 | 5 | 0 | 4 |

| + | 0 | 2 | 4 |
|---|---|---|---|
| 0 | 0 | 2 | 4 |
| 2 | 2 | 4 | 0 |
| 4 | 4 | 0 | 2 |

Wendy: And when you're doing 4, you need 0. Well.... Ooh.

Figure 3. Wendy's tables for  $\{0, 1, 5\}$  and  $\{0, 2, 4\}$ .

Wendy: You need 0, anyway. You need 4 though. [inaudible] So, 2 ... 'cause 2 and 4 is going to equal 0. Uh oh.

Wendy: It works! You don't.... It's closed. It's got an id-, everything has an identity element ... 0 is the identity element for all, each element. Well, they have to have the same identity element, but.... And it's got an inverse. (lines 196-202)

Wendy had found a subgroup of  $Z_6$ , but she was able to conclude that it was a subgroup only after she had completed both the operation table and her table-based verifications of the group axioms. For the first time in the interview, she considered several axioms in quick succession, although her explanations were somewhat muddled. Her language suggests that she was surprised—an impression that she confirmed when I asked whether there are any other subgroups of  $Z_6$ : “I don't know; I'd have to play and try. I just found one; I didn't think that we could find one, but I just found one” (lines 212).

### Observations

Wendy's reasoning about groups and subgroups was largely external, often requiring that relevant portions of the table be present before her eyes without extraneous information interfering with her perception. When considering whether  $\{3, 5\}$  was a subgroup, she covered up the 4, and when building a subgroup with  $\{1, 5\}$ , she created a new table separate from the  $Z_6$  table. In large measure, the operation table was the group for Wendy, although later in the interview she began to separate the group from the table, as evidenced by a suggestion that the table she called  $4Z_3$  was a rearrangement of the table for  $\{0, 2, 4\}$ , which she called  $2Z_3$ . The operation table both supported and limited Wendy's ability to reason about groups and subgroups. On the one hand, the table helped her see quickly the central issue about considering  $Z_3$  to be a subgroup of  $Z_6$ . On the other hand, her reliance on the table made it difficult for her to find subgroups.

A symptom of the external, table-based nature of Wendy's reasoning was that she often considered only one group axiom at a time when reasoning about groups and subgroups. Toward the end of the interview, however, she had developed more fluency and was able to move more quickly among the axioms. Considering the axioms multiply and flexibly might be described as a matter of proficiency and fluency with the group axioms and with the particular examples, which may be a result of gradual internalization of some of the external processes that were based in the table.

In a later interview, Wendy continued to struggle with the distinction between a group and its representation in a particular operation table. She recognized isomorphisms among various groups of order 4 and had a strong sense that there are only two such groups (up to isomorphism), but her methods remained largely external, relying upon the appearance of the operation tables and upon processes of renaming and reordering elements in those tables.

## Results

Operation tables served to mediate abstraction for the students in this study in that they worked with a concrete representation to gain access to abstract objects and their properties. A group's operation table makes the group more concrete by making aspects of its form directly visible. Furthermore, by squinting one's eyes or coloring the operation tables by elements or by cosets, the abstract group—of which the particular table is an instantiation—can almost become visible. Abstracting the essence of a group from an instantiation seems a quintessential example of an activity that requires reflective abstraction—abstraction based on action (i.e., operations) alone. With the help of the operation table, however, perhaps only empirical abstraction is required. Thus, the table becomes both a tool for reasoning and an object of reflection. Under Wilensky's (1991) view of abstractness as a measure of one's familiarity with a situation, the table serves to increase one's familiarity, thereby making the abstract more concrete.

Operation tables served a metaphorical role for many students in that the tables supported their reasoning and helped them think of groups as objects. For some of the students in the study, the table *was* the group rather than a representation—a metonymic substitution of the concrete for the abstract. Their reasoning seemed to be largely external, in the sense that it was based *in* the table and in procedures that required that the operation table be present rather than in reflection on the binary operation. Most of the group axioms, for example, were verified through such table-based procedures. The cancellation laws (e.g.,  $ab = ac$  implies  $b = c$ ) became embodied in the requirement that each element appears exactly once in any row or column.

The table served also to heighten the students' sense of anticipation about the way the calculations should turn out, similar to Boero's (1993) observation about the role of anticipation in algebraic manipulation. One student, for example, expected the coset  $\{5, 7\}$  to be its own inverse. Many students came to expect certain patterns in their operation tables and likened those patterns to cycles, which caused some potentially problematic connections with the cycle representations of permutations.

The prominence of the operation table helped explain the fact that students demonstrated strong connections between distinct concepts. For example, students sometimes confused the identity and inverse properties in part because finding the inverse of an element requires looking for the identity element in a particular row or column. Students confused commutativity and associativity in part because when an operation table is present, commutativity is more salient than associativity. Commutativity is quite visible through symmetry in the operation table, whereas associativity is more difficult to see and much more difficult to verify when the group is given by an operation table.

The operation table as metaphor has other limitations as well. First, it becomes cumbersome for large groups, and extending the metaphor to infinite groups requires

some sophisticated patterning abilities since it is not possible to write out the whole group table. Second, the students expected subgroups to occupy a corner of the table, probably because of reliance on Groups-Are-Sets and Set-Are-Containers metaphors. Third, writing down a group table requires one to choose an ordering of the elements, which sometimes made it difficult for the students to recognize isomorphisms and to think of the order as nonessential. Nonetheless, through experiences in renaming and reordering operation tables, the students began to separate the table from the group—the signifier from the signified—and thus began to develop concepts of abstract groups.

### Discussion

The results of this study suggest that the operation table can play a useful metaphorical role in students' thinking about group theory because of the conceptual support that the metaphor can provide. This paper discusses three implications. First, the results of this study provide insight into and support for Peirce's (1955) semiotics, in which a sign becomes a sign when it is interpreted by someone as a representation of something else. In the case of Wendy, at first each operation table *was* a group. She began to develop understanding of groups as abstract objects only through considerable conceptual struggle, supporting Sfard's (2000) contention that "The transition from signifier-as-object-in-itself to signifier-as-a-representation-of-another-object is a quantum leap in a subject's consciousness" (p. 79).

At the same time, the results of this study call into question the developmental relationship between process and object conceptions. Through use of the operation table, some of the students appeared to have strong object conceptions of groups with relatively weak process conceptions. One possible explanation is that the tables were not objects but pseudo-objects for these students (Sfard & Linchevski, 1994; Zandieh, 2000). The processes were largely external in the sense that the students used procedures that depended upon the presence of the operation table. Another possible explanation is that through the use of the operation table, the developmental trajectory was reversed, with process conceptions emerging slowly from object conceptions.

Finally, the results of this study provide additional support for the use of multiple representations as a way of building understanding of abstract mathematical concepts and objects. Thompson (1994) observes:

Our sense of "common referent" among tables, expressions, and graphs is just an expression of our sense, developed over many experiences, that we can move from one representational activity to another, keeping the current situation somehow intact. Put another way, the core concept of *function* is not "represented" by any of what are commonly called the multiple representations of function, but instead by our making connections among representational activities. (p. 39)

In this study, the students similarly developed abstract conceptions of objects and concepts in group theory by translating among what are taken to be equivalent representations of the same object.

# CHARACTERIZING SECONDARY STUDENTS' UNDERSTANDING OF MEASURES OF CENTRAL TENDENCY AND VARIATION

Randall E. Groth  
Illinois State University  
regroth@ilstu.edu

The purpose of the study was to begin the construction of a framework to describe secondary students' statistical thinking. Semi-structured clinical interviews were used to assess four secondary students' thinking about measures of central tendency and variation. It was found that the research-based Middle School Students' Statistical Thinking (M3ST) framework adequately characterized much of the thinking exhibited by students during the interview sessions. However, as a result of the analysis of the clinical interviews, three descriptors related to students' understanding of the relationship between sample means and population means were proposed for addition to the M3ST framework for use with secondary students. Also, a fifth level of thinking was proposed for addition to the M3ST framework for use with secondary students, since some of the interview subjects demonstrated a higher level of thinking than the highest level described in the existing framework.

It is becoming more widely recognized among the mathematics education community that in today's information-driven society, no student should leave high school without engaging in the study of statistics. It is no longer adequate for high school students to take a sequence of courses designed only to prepare them for the study of calculus. Statistical reasoning is essential for all students, regardless of what occupation they may choose to pursue (Gal & Garfield, 1997). Statistics play a key role in shaping policy in a democratic society, so statistical literacy is essential for all citizens in order to keep a democratic government strong (Wallman, 1993). Recognizing the key role statistics play in modern society, in its *Principles and Standards for School Mathematics*, the National Council of Teachers of Mathematics (NCTM, 2000) recommends that "by the end of high school students have a sound knowledge of elementary statistics" (p. 48).

The study of statistics in high school has gradually become more common over the course of the past decade. On the student questionnaire given with the 1990 National Assessment of Educational Progress (NAEP), 87.6 percent of all twelfth graders indicated that they had not taken probability or statistics, but by the 1996 NAEP that number had dropped to 79.2 percent (Shaugnessy & Zawojewski, 1999). In the late 1990's, reform curricula funded by the National Science Foundation (NSF) emerged at the secondary level integrating the teaching of statistics with the teaching of traditional topics from algebra and geometry (Alper, Fraser, Fendel, & Resek, 1998; Hirsch, Coxford, Fey, & Schoen, 1998). Even traditional algebra textbooks have begun

to include statistical topics alongside algebraic topics (e.g., Collins, 2000). The subject of elementary statistics appears to be gradually taking root at the secondary level.

As the study of statistics becomes more common at the high school level, it is imperative that the research base for advising curriculum design, instruction, and further research be expanded. Extensive research has been done of students' understandings of topics traditionally included in secondary school curricula, such as algebra and functions (Chazan, 2000; Sfard & Linchevski, 1994; Tall, 1992; Vinner, 1985), geometry (Burger & Shaughnessy, 1986; Fuys, Geddes, & Tischler, 1988; van Hiele, 1986; Usiskin, 1982), and calculus (Ferrini-Mundy & Guadard, 1992; Heid, 1988; Orton, 1983; Thompson, 1994). Since statistics is a relatively new topic in secondary school curricula, research about how high school students think about the subject is not as well developed. In fact, it is only within the past decade that research investigating how students handle data has accumulated in any substantial amount (Shaughnessy, Garfield, & Greer, 1996).

One way to help the various emerging efforts to expand the teaching of statistics at the secondary school level to be successful in enhancing students' understanding is to conduct research directed toward constructing a framework that describes the statistical thinking of high school students. Such research-based frameworks are vital for advising curriculum and instruction (Cobb et al., 1991; Resnick, 1983). The purpose of this study was to begin the construction of a framework to describe secondary students' statistical thinking by characterizing secondary students' understanding of measures of central tendency and variation. Research-based frameworks have already been constructed for describing the statistical thinking of elementary and middle school students (Jones et al, 2001; Mooney, 2002). This study marks the beginning of the process to extend that line of research to the secondary level.

### **Theoretical Perspective**

This study seeks to begin the process of extending the Middle School Students Statistical Thinking (M3ST) framework (Mooney, 2002) to the secondary level. The M3ST framework describes levels of statistical thinking across four processes: describing data, organizing and reducing data, representing data, and analyzing and interpreting data. The organizing and reducing data section of the M3ST framework (non-italic print in fig. 2) describes how middle school students think about measures of central tendency and variation. The focus of the current study was to investigate the adequacy of the organizing and reducing data section for describing secondary students' thinking about measures of central tendency and variation. The two major research questions in this study are: 1) To what extent do the descriptors in the M3ST framework characterize secondary statistics students' understanding of measures of central tendency and variation? and 2) What changes in the descriptors, if any, are necessary to characterize the understanding of secondary statistics students?

The M3ST framework is based upon a Neo-Piagetian model of development described by Biggs and Collis (1982). According to the Biggs and Collis model, human development follows the stages, or developmental “modes,” of: sensorimotor, ikonic, concrete-symbolic, formal, and post-formal (Biggs & Collis, 1991). As humans attain each mode, their thought processes are qualitatively different from those of previous modes. Within each mode, three cognitive levels (unistructural, multistructural, and relational) cycle and represent shifts in the complexity of students’ reasoning. There are also two cognitive levels serving as “bookends” for each mode: the prestructural, which is related to the previous mode, and the extended abstract, which is related to the next mode. The M3ST framework contains four levels of thinking which are isomorphic to cognitive levels described in the Biggs and Collis (1982) Structure of the Observed Learning Outcome (SOLO) Taxonomy. More precisely, level 1 in the M3ST framework, described as “idiosyncratic” thinking, corresponds to the prestructural level in the SOLO Taxonomy; Level 2 in the M3ST framework, called “transitional” thinking, corresponds to the unistructural level (within the concrete-symbolic mode); Level 3, “quantitative,” corresponds to the multistructural level; and Level 4, “analytical,” corresponds to the relational level. Mooney (2002) hypothesized the existence of a fifth level of thinking, which would correspond to the extended abstract level in the SOLO taxonomy, but observed no such level of thinking among the middle school students he interviewed. This fifth level of thinking, in terms of the SOLO taxonomy, would represent a shift from concrete-symbolic to formal reasoning, and most students are not likely to function at this level of thinking until their secondary school years.

## **Method**

### **Instrument**

Interview questions designed to elicit students’ thinking about measures of center and variation were constructed by consulting the existing body of literature concerning students’ thinking about measures of center (Mokros & Russell, 1995; Watson & Moritz, 2000a) and variation (Shaugnessy, Watson, Moritz, & Reading, 1999; Tversky & Kahneman, 1982). A total of four interview tasks (fig. 1) were written. The first task was designed to assess students’ understanding of the relationship between population means and sample means. The second task required students to compare three data sets, each of which had the same mean and median. The third task consisted of three problems which could possibly be solved using various different measures of center and spread. The final task asked students to approximate the mean, median, mode, and standard deviation for each of four different distributions.

### **Participants**

Semi-structured clinical interviews using the written tasks were used to assess the statistical thinking of two male and two female students from an AP Statistics class. At the time of the interviews, the students had just completed the study of the first two

- 1) The average ACT score at Clintonville University is 23. The university only admits students with a score of at least 18. The university gives scholarships to those students who score 36, the highest possible score on the ACT. A random sample of 10 students' scores is taken. Which data sets are possible scores of the 10 students?

- A) 19, 21, 27, 20, 18, 31, 34, 21, 20, 19
- B) 18, 24, 19, 38, 27, 23, 20, 18, 24, 18
- C) 32, 36, 28, 31, 29, 28, 30, 32, 29, 29
- D) 18, 23, 25, 16, 27, 24, 19, 32, 28, 18
- E) 19, 18, 20, 19, 18, 21, 18, 18, 18, 19

- 2) A consumer protection group determined the number of hours three different brands of batteries lasted in five different cassette recorders. Below are listed the number of hours each brand of battery lasted in the five different recorders. Judging from the data given below, which two brands do you think are most similar in performance? How would you convince someone else of your choice?

|          | <u>Recorder 1</u> | <u>Recorder 2</u> | <u>Recorder 3</u> | <u>Recorder 4</u> | <u>Recorder 5</u> |
|----------|-------------------|-------------------|-------------------|-------------------|-------------------|
| Brand A: | 10                | 15.5              | 20                | 24.5              | 30                |
| Brand B: | 14.0              | 19                | 20                | 21                | 28                |
| Brand C: | 11                | 16                | 20                | 24                | 29                |

- 3) How would you determine:

- a) The typical height of people in a third grade class?
- b) The typical height of people in an elementary school?
- c) Which two classes had the most similar performance on a test given to 10 different classes in a school building?

- 4) Give an approximation for the mean, median, mode, and standard deviation for each of the following distributions.

a)

Figure 1. Interview tasks (Part 1).

chapters of a popular AP Statistics textbook (Yates, Moore, & McCabe, 1999). The first two chapters of the text introduce various formal measures of center and spread. The students were recommended for interviews by their teachers, who felt that they represented a fairly wide range of statistical thinking ability. AP Statistics students were chosen for the current study in the hope that their studies would allow some of them to display higher levels of thinking than the middle school students studied by Mooney (2002), and therefore serve to extend the M3ST framework to characterize higher levels of thinking.

Figure 1. Interview tasks (Part 2).

### Procedure

Each interview session lasted approximately 45 minutes. Each interview item was presented on a separate piece of paper to each student one at a time. I read each question aloud in an attempt to ensure no tasks were misread or misinterpreted. Students were told they could write as much or as little as they pleased on each task sheet they were presented. Students were given a TI-83 calculator with all lists cleared and told they could use the calculator as much or as little as they pleased in answering the interview questions. I took field notes as students gave responses, audiotaped each interview, collected students' written work at the end of each interview, and then transcribed each interview.

### Data Sources and Analysis

The primary data for the study came from the clinical interview sessions. Analysis of data from the interviews followed methods described by Miles and Huberman (1994). To begin the analysis, I wrote reflective notes on interview transcripts shortly after each session. The interview transcripts, reflective notes, field notes, and the students' written work were used to write vignettes of each interview session. Next, a 4 x 4 matrix was constructed with a different student's name heading each column, and a different level of thinking from the M3ST framework heading each row. Indi-

vidual responses to interview questions were cut from the interview transcripts and placed within the matrix. In this manner, each response was assigned a level of thinking within the M3ST framework. I refined the assignment of responses to levels by consulting the written vignettes and the descriptors in the existing M3ST framework. Responses which did not fit within the scheme of the M3ST framework were not placed within the matrix, but were set aside and categorized to aid the formulation of essential components not currently included in the M3ST framework.

### Results

The M3ST framework adequately characterized much of the thinking exhibited by students during the interview sessions. The existing descriptors in the organizing and reducing data section of the M3ST framework proved to be accurate descriptors for many of the interview responses. Therefore, data gathered from the current study did not result in the revision of any existing descriptors.

However, three descriptors were proposed for addition to the M3ST framework for use with secondary students. During the interviews, three distinct levels of thinking about sampling situations emerged in response to interview question 1 which were not described by the existing framework. At the lowest level of thinking observed in response to the first interview task, two students felt that the mean of a small sample must exactly match the mean of the population from which it is drawn. This was considered a “multistructural” response within the SOLO Taxonomy, since “in multistructural responses, closure is determined when (two or) more aspects are perceived, but since those aspects are not interrelated, inconsistency may result” (Biggs & Collis, 1982, p. 28). In this case, students perceived something of the nature of random sampling and measures of center, but came to an incorrect conclusion from not being able to relate the two concepts. At the next level, two students acknowledged that the mean of a small sample may vary slightly from the mean of the population from which it is drawn. This was considered a relational response, since a student responding relationally “will come up with a definite answer (closure), possibly an excellent answer for that context, but it will not do for other contexts (i.e. an over-generalization may be made)” (p. 28). In essence, answering that the mean of a sample will vary only slightly from the mean of the population from which it is drawn is an excellent answer for most situations. However, it is an over-generalization to think that the two means will vary only slightly in any given case. None of the students interviewed exhibited a higher level of thinking, at which one would acknowledge that the mean of a small sample may vary greatly from the mean of the population from which it is drawn. Such a response would be typical of an extended abstract response, which “sets out principles and heavily qualifies their application to a given situation” (Biggs & Collis, 1982, p. 28). Descriptors for each of these three levels of thinking were formulated and proposed for addition to the framework. These new descriptors and how they may fit into the current M3ST framework are shown in italics in figure 2.

A fifth level of thinking was also proposed for addition to the M3ST framework for use with secondary students. In the existing framework, at the fourth level of thinking in the process of organizing and reducing data, students are able to “describe data using a valid and correct measure of center.” One student interviewed demonstrated a higher level of thinking by going beyond using just one valid and correct measure of center to describe data. He consistently gave correct discussions of the relative merits of using different measures of center to describe data sets. None of the students interviewed were able to consistently give correct discussions of the relative merits of using different measures of spread to describe data sets, but the thinking of students who are able to do so would not be adequately described by the fourth level of thinking in the M3ST framework. In essence, in order for the M3ST framework to be useful in characterizing secondary students’ thinking about measures of central tendency and variation, a fifth level of thinking must be added. This proposed fifth level of thinking,

| <b>Organizing and Reducing Data</b><br>Organizing and reducing data involves arranging, categorizing, or consolidating data into a summary form. In general, students performing or explaining questions, tasks, or activities which involve organizing and reducing data will... |  |

Figure 2: Possible revisions (in italics) to the organizing and reducing data section of the M3ST framework (Mooney, Langrall, Hoffbauer, & Johnson, 2001) for use with secondary students.

with its associated descriptors, is shown in italics in figure 2. It is isomorphic to the extended abstract level of thinking in the SOLO taxonomy, since, according to Biggs and Collis (1982), "The student giving an extended abstract response can entertain alternative outcomes: He is not forced, as are the others, to come to a definite closure or conclusion" (p. 28). In this case, students at the fifth level of thinking show the ability to consider various measures of spread and central tendency as appropriate, and not necessarily settle on only one. The name "extended analytical" to describe this level of thinking has been borrowed from Mooney (2002).

### Discussion

The current study raises a number of issues for further investigation. First of all, further research must be done to investigate secondary students' notions about sampling from a population. It is quite startling that two students involved in the study felt that the mean of a random sample must exactly match the mean of the population from which it is drawn. It is impossible for students to learn about inferential statistics in a meaningful manner if they cling to such a misconception. In order to comprehend inferential statistics, students must understand that the means of all possible samples drawn from a population are not all the same, but rather form a sampling distribution. Current curricular guidelines for secondary statistics (NCTM, 2000; College Board, 2001) call for secondary students to understand and work with sampling distributions. Watson and Moritz (2000b) suggest that students be exposed to sampling concepts across their years of schooling in order to develop understanding. Future studies need to examine the effectiveness of activities designed to dispel students' misconceptions about sampling situations.

It is also striking that none of the students interviewed exhibited higher than level 4 thinking about measures of spread. Some students even viewed standard deviation simply as a formula, and did not think of it as a measure of spread. This situation is analogous to Mokros and Russell's (1995) findings about children's conceptions of the arithmetic mean. Some of the children studied by Mokros and Russell did not think of the mean as being an indicator of the center of the data set. Instead, they viewed the mean simply as an algorithm. This view prevented them from attaining a level of thinking at which they would understand various measures of center to describe a data set, and then choose which one was most appropriate to use for any given situation. Some students in this study were in a similar situation in their thinking about standard deviation, since they did not conceive of it as a measure of spread, and hence could not possibly evaluate how the measure could be used in order to gauge spread in any given situation. Teachers and researchers need to design and implement appropriate instruction about measures of spread in order to prevent students from developing impoverished procedural understandings of concepts such as standard deviation.

Finally, studies involving tasks designed to investigate the adequacy of the other areas of the M3ST framework for describing secondary students' thinking must be

conducted. The current study focused mainly upon investigating aspects of the Organizing and Reducing Data section of the framework. We now need to gather information about the adequacy of the other sections, which describe how students analyze, represent, and describe data. In investigating the other sections, it may be found that some of the descriptors characterizing levels of thinking formulated in this study could be refined, or perhaps even moved to other sections of the framework. A more complete framework for describing the statistical thinking of secondary students needs to be developed in future studies.

It is important that, during the study of algebra at school, students have opportunities to deal with situations in which symbols, operations and rules make sense. The formulation of functions, as the result of the exploration and recognition of patterns, is a process that is intrinsically linked to modeling and in which students can learn new forms of expressing their mathematical thought and develop a better understanding of the ideas involved. This paper makes some reflections about the process of recognizing patterns and reports the work done by students who were given tasks related to the construction and analysis of recursively defined functions and explicitly defined functions. The results of the analysis show that students have some difficulties in the process of symbolizing successions and patterns, especially when these emerge in the process of solving a task that involves a contextual situation.

### Introduction

One aspect on which mathematics education has centered its attention is in the design and implementation of tasks that permit the student to become actively involved in a real mathematical experience. Tasks that motivate reflection and communication of important mathematical ideas and in which students' resources and previous experiences are the basis for extending and strengthening their knowledge and understanding of mathematics.

The type of tasks that are proposed to students in the classroom contributes significantly to form a vision that students have of the discipline (Romberg & Kaput, 1999). The tasks that allow students to reflect, explore and communicate, besides strengthening the understanding of ideas, can promote a new vision of mathematics as an interesting, powerful discipline, in which knowing makes sense.

In *Principles and Standards for School Mathematics* of NCTM, the standards for high school state that students should begin to experiment and understand aspects related to the structure and form of mathematics, including the analysis and use of a wide range of functions to model real-life situations (NCTM, 2000, pp. 287-288). The formulation of recursively defined functions and explicitly defined functions, as a means to express the properties and characteristics of a succession, permits students to extend and strengthen their understanding of a variety of mathematical concepts. These functions are also essential processes for the study of calculus, discrete mathematics, and other sciences.

The recognition of patterns is not an unfamiliar process for high school students. It is taught from elementary levels, beginning with the ordering of natural numbers and counting by  $k$ s integers (by 1s, by 2s, etc.) to promote processes of reasoning that will permit later development of the skills of generalization and abstraction. These previous experiences can constitute important resources for exploring and constructing models based on recursively defined functions (recursive models) as well as a powerful way of expressing relationships and analyzing properties of mathematical processes, operations and notions involved in the recognition of patterns.

The objectives of this paper are to reflect on the characteristics of pattern recognition itself and to report the work that students do when they face contextual situations in which the generation of numerical successions is a resource for the solution, and students are invited to construct recursive or explicit models for those situations.

### **Theoretical Framework**

Many studies (Carpenter & Lehrer, 1999) support the assumption that when students learn with understanding, they can use their knowledge flexibly in new situations. Heibert et al. (1997) define mathematical understanding in terms of the mental activity that unfolds when an individual makes connections between mathematical ideas. Carpenter and Lehrer (1999) propose five forms of mental activity from which understanding emerges: i) building relationships, ii) extending and applying mathematical knowledge, iii) reflecting on experience, iv) articulating what is already known, and v) appropriating mathematical knowledge.

In the design and implementation of task, opportunities must be taken so that students become involved in these forms of mental activity, in which knowledge and skills develop together as necessary resources in the process of solving a problem.

One of the expectations posed in the NCTM *Principles and Standards for School Mathematics* (2000) for high school algebra students is that they must have opportunities to “generate patterns using both recursively and explicitly defined functions” (NCTM, 2000, p. 395). One pattern is a rule with which elements of a succession of mathematical objects (for example, numbers or figures) are constructed, and, therefore, recognizing a pattern means discovering the rule.

In the process of recognizing a pattern, the student reflects and, in the first try, attempts to identify common characteristics and qualitative differences among elements that form the succession. She (or he) then tries to systemize these characteristics and *generalizes her ideas* to propose a pattern and test it to see if it is valid for the elements of a succession. Later, she tries to express the results in natural language and/or utter the rule mathematically. In this process, the generalization of ideas is a very important step, since it is at this moment that the student can be considered to have attained the systemization of her observations to describe a rule.

Of course, a numerical succession, expressed by only a few terms, as is commonly done, can have different rules of construction that can lead to mathematical

expressions that are not necessarily equivalent. For example, the expressions  $F_n = 3 \cdot 2^n$  ( $n=1, 2, 3, 4, \dots$ ) and  $G_n = n^3 - 3n^2 + 8n$  ( $n=1, 2, 3, 4, \dots$ ) are valid models for generating the terms shown explicitly in the succession: 6, 12, 24, 48, . . . ; however, the following term in the succession differs from one case to another ( $F_5=96$  y  $G_5=90$ ). In fact, Krutetskii (1976), in studies on the development of mathematical skills in the early 60s, states that if a student is capable of recognizing different forms of generating all of the given elements of a sequence and indicate some possible variations for the following elements, “this is an indication of a very high level of mathematical thinking” (Krutetskii, 1976, p. 151). We must acknowledge that in the process of pattern recognition there can emerge different rules of construction that, if they are not discussed and analyzed carefully, they can cause confusion for both students and teachers.

Pattern exploration can serve as a context for the introduction of different forms of expressing relationships and show that such relationships can be described correctly using different methods. That is, the regularities discovered in a succession can be systemized and uttered by means of rules or formulas that are algebraically different, some of which may be equivalent. For example, in the succession of the numbers 2, 4, 6, 8, 10, ..., a rule for the construction of the following term is “add two to the previous result”; another might be “multiply the number corresponding to the position by two.” Both of these are surely identified easily by high school students. Symbolically, they can be expressed as a recursively defined function,  $T_n = T_{n-1} + 2$ , with  $T_1 = 2$ , and  $n=1, 2, 3, 4, \dots$ , and as an explicitly defined function,  $T_n = 2n$ , with  $n=1, 2, 3, \dots$ .

Although students can discover a pattern, they seem to have difficulty when they try to express it symbolically (Franzblau & Warner, 2001). Even though the algebraic notions involved in the mathematical formulation of patterns of arithmetic and geometric successions are part of the basic algebra courses, it seems that the difficulty in expressing them lies not in the systematic generation of the objects of the succession, nor in not having algebraic notions, but in the *use* of symbols appropriate for the expression of the relationships and properties identified. Particularly, the recursive models are generally more natural forms of expressing the characteristics of a pattern (NCTM, 2000) and, therefore, can give meaning to the relationships between processes and functions. However, the symbols used to express these models mathematically (use of subscripts, or subscript notation) is not frequently incorporated and used in high school algebra courses, although it seems to be a very important resource for the development of a better understanding of the notions of both dependency and independency of variables and the concept of function (Franzblau & Warner, 2001).

### Subjects, Methods and Procedures

In this study we attempt to explore the ability of high school students to recognize and symbolize patterns. A qualitative research method was used, consisting of an analysis of the work done by students to solve each of four tasks proposed and notes of the observations made during the sessions of discussion.

These four tasks were given to seven students with average achievement who volunteered to participate in the exploration at the beginning of December 2001. These students studied the topic of functions as part of their algebra course at the high school Rector Hidalgo in Morelia, Michoacán. Since our purpose was to promote the mathematical formulation of numerical patterns of arithmetic and geometric successions that emerge in specific situations, the participating students were encouraged to discover relationships and their mathematical formulation by asking them specific questions during the tasks.

The students first worked individually, reporting their work in writing and, later, they discussed and analyzed their solutions with the group and their instructor. Two sources of data were used to gather the information: (a) the individual work reported in writing by the students and (b) the notes of observations made on the participation of the students during the discussion after solving the tasks. In both cases, special attention was paid to the following aspects:

- i) The interpretations that the students give to the situations posed in the tasks.
- ii) The systemization and organization of the data in tables or graphs.
- iii) The identification of operational characteristics and properties of the process.
- iv) The possible proposals of solution and the symbols used.
- v) The recognition of equivalences and differences among the functional relationships proposed.

The application of the tasks was done in four sessions of approximately one hour for a period of two weeks, combined with sessions of discussion after each of the sessions of application.

### Results

Some of the characteristics we tried to give to the tasks were the following:

- (a) that no sophisticated mathematical resources be required for the solution;
- (b) that the students be given the opportunity to construct and reflect on their own methods of solution;
- (c) that the use of different strategies and procedures be permitted;
- (d) that calculators be permitted as a tool for exploration and testing the results; and
- (e) that the tasks provided be sequenced in the construction and analysis of recursive and explicit models, progressing gradually as the students advance in the solutions.

In general terms, although the students use recursive type procedures and construct lists of data, they tended to focus on the calculated results instead of the process.

Only after instructing them on the use of notation with subscripts and encouraging them to look for common operations and procedures, did they try to give a pattern, exhibiting some difficulty in expressing it symbolically. Also, although at the end of the exploration some students could give recursive and explicit patterns, they justified the relationship between these saying that “in both cases we get the same results,” without giving a reasonable explanation of why these results are equal. The use of subscripts and symbolic formulation of patterns seems to be strengthened as students progress in the solution of the tasks, although the relationship between recursive and explicit expressions could not be justified mathematically. In the following section we present the results of the analysis of each task.

### Task 1. Population growth.

This first task served as context to explore the ways in which the students generate and name the elements of a succession; that is, an attempt was made to inquire into the resources students use when they work on tasks that require generating a numerical succession. All of the students used a recursive process to arrive at the solution, constructing lists of numbers that, in some cases, they organized in a table.

Although for this problem students were not asked explicitly to obtain a general solution, three of them showed a tendency to try to express a symbolic relationship based on previous numerical calculations.

| $2003 \rightarrow 97,483,412 \text{ hab} + 7.5\%$ $\vdots$ $A_n \rightarrow 97,483,412 \text{ hab} + (2.5\%)(X_n)$ $A_{\text{año}(2010)} \rightarrow 97,483,412 \text{ hab} + (2.5\%)(10)$ | $2003 \rightarrow 97,483,412 + 2.5\{2.5[2.5(97,483,412)]\}$ $P_n \rightarrow 97,483,412 + 2.5^n(97,483,412)$ $2010 \rightarrow 97,483,412 + 2.5^{10}(97,483,412)$ |
| <b>Claudia</b>   | <b>Pedro</b>  |

Figure 1. Solutions (partial) by Claudia and Pedro for task 1

One of the students who organized the information in a table made a graph of his results and during the discussion session commented that the graph looked like a curve that “is becoming horizontal,” but without recognizing a specific analytical relationship to represent it.

Claudia and Pedro, for example (See Figure 1), constructed explicit relationships in which, in the first case, Claudia uses a notation that tends to be more functional,  $[A_{\text{año}(2010)} = 97,483,412 \text{ hab} + (2.5\%)(10)]$ , with which she means to express: Population in the Year(2010) =  $97,483,412 + (0.025)(10)(97,483,412)$ . In contrast, Pedro uses subscripts to denominate the general term. Both solve the problem with their models, although they exhibit some difficulty in interpretation and symbolization.

An important part of the activity was discussion and analysis of the solutions they obtained. This gave the instructor opportunity to use and show possible ways to denote the terms that were generated by the students during the process of solution and to compare several solutions while encouraging students to reflect on how reasonable their solutions were. In these discussion sessions, other arithmetic and geometric successions, proposed by both students and instructor, were analyzed.

### Task 2. Putting nails.

The application of the second task (See appendix) was an attempt to explore the ability of the students to obtain the result of addition of a succession resulting from the situation presented in the task. Although the students, in the discussion sessions previous to the application of this task seemed to be aware of the usefulness of the symbolic denomination of the terms to generate a pattern, several of them (four) did not use symbolic notation during the process of solution. As in the previous task, they generated an ordered list of calculations and/or numerical results recursively, adding one by one to obtain the solution.

In contrast, two students (Pedro and Roberto in Figure 2) use subscript notation to symbolize the terms of the succession. Pedro, using only a few terms, could discover and symbolize an explicitly defined pattern [ $C_n = 10 + 15(n-1)$ ], which he used to calculate the terms and, later, their sum (as can be observed in Figure 2, Pedro uses the technique of reversibility of the addends to calculate the sum). However, he treats the two parts of the task separately and, in the second part, in which a pattern is explicitly asked for, he proposes a different relationship and expresses the sum with each of the terms symbolically. It seems that the contextual situation, in itself, led him to construct a correct model, while, when a relationship is explicitly asked for, Pedro has difficulty with symbolization.

Roberto, on the other hand, first generates the terms of the succession in numerical form and responds to the first part of the task, adding one by one. In the second

| Pedro   | Roberto   |

Figure 2. Pedro and Roberto's solutions for task 2.

part (shown in Figure 2), he proposes  $P_n = P_{n-1} + 15$  as the pattern and test his proposal by applying it to a few cases. This proof seems to lead him to an explicit relationship, but he has difficulties in symbolizing. Like Pedro, he expresses the sum with each of the terms symbolically. The use of "x" to express the pattern, in both cases, is due to the fact that in each task the situation asked for is given in terms of this letter (See appendix).

In this task, only one student attempts to symbolize the recursive process to establish a pattern (See Figure 3). However, like Pedro, she needs to calculate each of the terms to arrive at establishing the sum.

The processes carried out by the students afforded the possibility that the discussion following the application center mainly on the analysis of the procedures and models proposed, since these involved both recursive and explicit rules for the succession (not so for the sum of the terms of the succession). Special attention was made to the variety of models that can be generated for one situation as well as to the advantages that, in some cases, have the explicit over the recursive models. Also the processes that are followed to obtain the terms of the succession were explored, as much in a recursive model like in an explicit one. One of the students pointed out: "[in the recursive model,] *the operations are easier, but it is necessary to work more* [than in the explicit model]", concluded that, for the examined cases, the explicit models were "faster".

$$\begin{aligned}
 T_1 &= 10 \text{ ¢} \\
 T_2 &= T_1 + 15 \text{ ¢} = 10 + 15 = 25 \\
 T_3 &= T_2 + 15 \text{ ¢} = 25 + 15 = 40 \\
 T_4 &= T_3 + 15 \text{ ¢} = 40 + 15 = 55 \\
 T_5 &= T_4 + 15 \text{ ¢} = 55 + 15 = 70 \\
 T_6 &= T_5 + 15 \text{ ¢} = 70 + 15 = 85 \\
 T_7 &= T_6 + 15 \text{ ¢} = 85 + 15 = 100 \\
 &\vdots \\

 &\underline{3.65 (24)} = \$ 43.80 \\
 &2
 \end{aligned}$$

Figure 3. Adriana's solution for task 2.

**Task 3. Printing costs.**

This task involves a situation that, at first, looks similar to the previous one (See appendix). While the process of counting the terms in the case of task 2 was one by one (1 nail, 2 nails, etc.), in this task counting 500 by 500 (1000 flyers, 1500 flyers, etc.) imposes certain difficulties for the students during the solution since they need to generate not only a succession for the cost of production but also for the number of flyers involved. Figure 4 shows Adriana's process of solution, a case that is typical of the work done by five of the students.

$$P_0 = 100 = 1000$$

$$P_1 = 100 + 20 = 1000 + 500$$

$$P_2 = 100 + 20 + 20 = 1000 + 500 + 500$$

$$P_n = 100 + n(20) = 1000 + n(500)$$

$$P_0 = 1000 \quad P_1 = P_0 + 500 \quad P_2 = P_1 + 500$$

$$P_n = P_{n-1} + 500$$

Nota: Para determinar el número de series de volantes extra se divide el número de volantes extra entre 500.  $\therefore n = \frac{P - 1000}{500}$

Figure 4. Adriana's solution for task 3.

In this solution, Adriana makes an attempt to match the number of flyers to their cost of printing, trying to equate the numbers (incorrectly). She generates two explicit models: one to quantify the number of flyers [ $P_n = 1000 + n(500)$ ] and the other for their cost of production [ $P_n = 100 + n(20)$ ].

In this task, two students again carry out a numerical process to calculate the cost and produce a pattern (explicit) as a solution.

Although all of the students use a variable ( $n$ ) that increases 500 by 500, they propose a solution that can be equivalent to  $P_n = 100 + 20(n)$  without mentioning additional conditions for  $n$ . Only two students (for example, see Figure 4) try to express symbolically the fact that  $n$  (number of flyers) is a quantity that increases 500 by 500, although they have problems expressing it.

During the discussions following the application (in three sessions of approximately one hour), the models proposed in the third and fourth tasks were analyzed. The characteristics of each situation were analyzed to highlight the differences and

the usefulness of the models. Processes of transformation from a recursive form to an explicit form were explored, in function of the observed operational characteristics as well as in terms of the notion of linearity in the recursive models in the case of some arithmetic and geometric successions.

#### Task 4. Recursive and explicit functions.

In this task the word *progressions* (See appendix) was used to refer to numerical successions since some of the students remembered that they had studied them with that name at some moment in their junior high algebra course. In general, most of the students (six) begin with the denomination of the terms as  $P_0, P_1$ , etc. (or some equivalent form), to later propose a pattern and test its validity with a few terms.

It seems to be that because of the fact that the terms of the succession are given explicitly in the task, the denomination of the terms is an important step in the solution (not so in the other tasks). The students, with no difficulty, propose a recursive model for the successions and, although for the second succession, the explicit model can be identified easily, the fact that a recursive formula was asked for first seems to have affected the process, since most of the students do not manifest, in their written work, having recognized the model. The students attempt to arrive at a recursive formula and, based on this, construct an explicit formula. Only one student (Pedro) shows an explicit pattern as a construction rule (See Figure 5), although he does not recognize it as such and tries to arrive at a formula by applying the algebraic algorithm (taught by the instructor in previous sessions) to transform a recursive relationship into an explicit one.

During the discussion following the application, it was necessary for the instructor to give an example of the solution to this task, emphasizing the process itself since all of the students attempted to use the algebraic algorithm (illustrated by Pedro's work in Figure 5) without reaching a conclusion.

Figure 5. Pedro's solution for task 4.

### Conclusions

The participating students had no difficulty in recognizing that the generation of numerical successions is a feasible procedure for arriving at a solution for the first three tasks. Although in this exploration, the students use recursive procedures when they attempt expressing a general result, they tend to do so in terms of an explicitly defined function. It seems that this tendency is due to the fact that the students had not had sufficient opportunities to use recursive models as mathematical resources to express their mathematical ideas and thought.

The students, although they pay attention during the process of solution, say that it “is boring because many operations are repeated,” focus mainly on the exactitude of their calculations and not on the procedure itself. Only after they reflect on this aspect can they perceive that this is an important aspect of the tasks.

The organization of the data generated in lists and tables was a common characteristic in the work of all of the students during the process of solution and, even though at that time they were learning to graph linear and quadratic functions using tables in their algebra course, only one student attempted representing the data with a graph.

One important aspect that encouraged reflection and communication of ideas was the variety of models generated by the students for the same task. The discussion of analogies and differences and the viability of the models generated gave the students the opportunity to appreciate the power of mathematics as a tool that allows a diversity of forms to express the same situation.

### **Appendix**

#### **Task 1**

The population in Mexico in the year 2000 was 97,483,412. If the population is growing at a rate of 2.5% per year, what will be the expected population of Mexico in the year 2010?

#### **Task 2**

A carpenter charged 10 cents for the first nail hammered in the construction of a fence. For each additional nail he charged 20 cents more than for the previous one. (Adaptation of the problem in *Algebra*, by Ress and Sparks, 1968)

- (1) How much money did the carpenter receive for hammering 24 nails?
- (2) If the carpenter wants to know how much to charge for an  $x$  number of nails, how could he figure it out?

#### **Task 3**

A print shop charges \$100.00 to print 1000 flyers and, for every 500 additional flyers, the charge is \$20.00 more than for the previous amount. Write a formula that would allow the printer to give quick estimates for the cost of printing  $n$  flyers. (The instructor indicated that a quick estimate consists of determining the cost directly from a given number of flyers, as was mentioned in the above discussion).

#### **Task 4**

Arrive at a recursive function and an equivalent explicit function for the following progressions:

- (1) 1, 5, 9, 13, . . .
- (2) 1, 2, 3, 4, . . .

## THE NATURE OF REFLECTIVE THINKING IN MULTIVARIABLE CALCULUS

Stephen J. Hegedus  
University of Massachusetts Dartmouth  
shegedus@umassd.edu

This paper reports on the vital role that reflective thinking plays in solving problems involving the mathematics of change and variation particularly multivariable Calculus. We report on how reflective thinking is one kind of self-regulatory (in the sense of metacognitive) thought mechanism. We present an outline of the results of a larger study, which investigated the metacognitive behavior of undergraduates solving problems in the Calculus.

### Theoretical Perspective

Metacognition refers to one's knowledge concerning one's own cognitive processes or anything related to them, e.g., the learning-relevant properties of information or data ... Metacognition refers, among other things, to the active monitoring and consequent regulation and orchestration of those processes in relation to the cognitive objects or data on which they bear, usually in the service of some concrete [problem-solving] goal or objective. (Flavell, Friedrichs, & Hoyt, 1970, p. 323)

This introductory quote by Flavell et al. set the scene for the next 30 years of inquiry into a complex cognitive mechanism which has received much attention as well as skepticism from various research traditions – from Neuroscience to Mathematics Education.

In Mathematics Education, Schoenfeld (1985, 1987) introduces metacognition through the Artificial Intelligence notion of *Control* as a cognitive strategy for resource allocation. Similarly, Garofalo & Lester (1985) introduce Control as related to metacognition:

Metacognition has two separate but related aspects:

- (a) knowledge and beliefs about cognitive phenomena, and
- (b) the regulation and control of cognitive actions. (p. 163)

Later Schoenfeld (1985) added a social dimension to the inquiry by observing a Vygotskian perspective on regulation-of cognitive strategies as a process by which we observe and internalize other people's similar thought mechanisms. Through operating in the *Zone of Proximal Development*, learners observe and replicate overt examples of how other people regulate their own problem-solving behavior. Through this practice, we proximally appropriate the behavior as part of own cognition in solving mathematical problems and specifically as part of our own revised regulatory behavior. Brown (1987) also observes this kind of "other-regulation" as being one of four historical

roots for metacognition. So, in attending to studying the metacognitive behavior of students learning mathematics it soon becomes apparent that the relevant literature in Mathematics Education and Cognitive Science (and the overlap) create a multifarious if not multi-headed beast that can lead to confusing lines of inquiry. While it is evident that metacognition is still studied in the fields of Neuroscience (Shimamura, 1994) the word is more so used in mathematics education rather than studied. It is evident in the National Council of Teachers of Mathematics (NCTM) *Standards* (2000) that instructional programs from pre-kindergarten through grade 12 should enable all students to *monitor* and *reflect* on the process of mathematical problem-solving:

Good problem solvers become aware of what they are doing and frequently monitor, or self-assess, their progress or adjust their strategies as they encounter and solve problems. Such reflective skills (called metacognition) are much more likely to develop in a classroom environment that supports them. (NCTM, p. 54)

It is not evident firstly, what this process of mathematical problem-solving is, hence enabling teachers to observe this behavior in their own students; nor secondly, what kind of classroom environments do actually support these skills as the Standards report. In our work, we have regarded the term metacognition as an umbrella term to embrace multiple perspectives such as Control (from AI), socially-constructed regulation (Vygotskian perspective) and self-regulation (Piagetian perspective).

Regulation-of thinking has played a significant role in Piaget's work (cf. 1978) and that of his contemporaries (Inhelder, Sinclair, & Bover, 1974; Karmiloff-Smith, 1979) where they refer to it as self-regulation and conceptual reorganization. Karmiloff-Smith & Inhelder's ideas explain how these mechanisms are characterized by the internal pressures to systematize, consolidate and generalize knowledge. Following our initial pilot work and study, our analysis highlighted the necessity to concentrate on this one strand of metacognition which offered us a suitable theoretical perspective given the nature of the learners we were studying and our research design.

Garofalo & Lester (1985) cite some evidence of *knowledge-of* thinking. They claim that older children realize that memory ability differs between pupils and that some realize that they can recall better than other individuals. Our pilot work showed similar evidence of this type of thinking and that self-regulatory cognitive strategies were far more apparent.

The main piece of empirical work (Hegedus 1998) further enhanced the meaning of self-regulation in advanced mathematical thinking by observing and verifying four particular strands of this type of metacognition: *Reflection*, *Organization*, *Monitoring* and *Extraction* of mathematical resources. In Hegedus (2001), we reported on the role of organizational thinking in the integral Calculus. This refers to the planning behaviors that a problem-solver engages in, in both the exploratory phases and the execution phases of a problem. We now outline the method of data collection and analysis and

then report on another strand of self-regulatory thinking outlined above; the nature of *reflective thinking* particularly when dealing with problems in the Calculus of many variables. As stressed in our previous report, our main theoretical perspective here is grounded in the nature of the mathematics that our students are learning. In detailing the nature of the students' problem-solving behavior in terms of their self-regulation we are examining how particular aspects of the mathematics of multivariable Calculus calls for particular mathematical cognition. Hence our study interprets psychological behavior in terms of mathematical procedure, conceptualization and execution of method.

### Methods of Data Collection

Building on the work of Schoenfeld (1985), a pilot study was completed using a think-aloud protocol analysis to observe the role of *knowledge-of* and *self-regulatory* thought processes by undergraduate mathematicians. Our initial research aims focused on highlighting what kind of metacognitive activities the undergraduate students exhibited and how effective these were in their work. The Schoenfeld methodology proved most effective in attending to our primary research aims. We used a method of protocol analysis to focus on the decision-making processes at the executive level or control level. Schoenfeld highlights, in chapter 9 of his book, how this method provides ways of 'identifying three classes of potentially important decision making points in a solution':

1. Decisions at the control level are those that affect the allocation or utilization of a substantial amount of problem-solving resources (including time). It is thus appropriate to look for executive decision-making at points in problem solutions where there are major shifts in resource allocation.
2. The second type takes place when either new information or the possibility of taking a different approach comes to the attention of the problem solver(s).
3. The third category of decision-making points is far subtler. These are times in a solution where nothing has gone catastrophically wrong, but when a string of minor difficulties indicates that it is probably time to consider something else.

We adhere to Schoenfeld's method of data collection and analysis by obtaining verbal data of think-aloud accounts by our respondents, which we then record and transcribe. Each item of dialogue is then numbered. We then parse the protocol into six episodes and using the numbering system make the data more referable. An illustration of the parsing of the solution process (see <http://merg.umassd.edu/heg/thesis>) was derived by a consensus opinion of a team of three undergraduates working with Schoenfeld. The team had been trained in parsing the data in this way and the results were found to be very reliable. These are then plotted on a time-line diagram to offer a representational image of how the solver changed problem-solving states with respect

to time (see figure 1) completed in Excel. The six states are *Reading, Analyzing, Exploring, Planning, Implementing, and Verifying*. Triangles are used on top of the bars to show times of overt management activity – we did not attend to this final detail, as the respective activities were too numerous to illustrate.

Schoenfeld (1985, p. 297-301) outlines a description of the six episodes and associated questions, which are relevant to our analysis. These episodes refer to particular behavioral states, under which Schoenfeld believed that most problem-solving activity fell.

In his analysis Schoenfeld includes local assessments and introduction of new information with other overt managerial behaviors. He describes managerial behaviors to include:

[S]electing perspectives and frameworks for working a problem; deciding at branch points which direction a solution should take; deciding in the light of new information whether a path already embarked upon should be abandoned; deciding what (if anything) should be salvaged from attempts that are abandoned, or adopted from approaches that were considered but not taken; monitoring and assessing implementation “on-line” and looking for signs that executive intervention might be appropriate; and much, much more. (Schoenfeld, 1985, p. 152)

We use the time-line diagrams to give an overview for the solution attempts of our students across a variety of problems as well as comparison with expert’s solutions we similarly categorize and analyze. We then utilize the questions set out by Schoenfeld for analyzing the times of transition between episodes and the times where new information and local assessments occur. These include:

#### **New-Information and Local Assessments**

- N1: Does the problem-solver assess the current state of his knowledge? (Is it appropriate to do so?)
- N2: Does the problem-solver assess the relevancy or utility of the new information? (Is it appropriate?)
- N3: What are the consequences for the solution of these assessments or the absence of them?

#### **Transition Points**

- T1: Is there an assessment of the current solution state? Since a solution path is being abandoned, is there an attempt to salvage or store things that might have been valuable in it?
- T2: What are the local and global effects on the solution of the presence or absence of assessment as previous work is abandoned? Is the action (or lack of action) taken by the problem-solver appropriate or necessary?

T3: Is there an assessment of the short- and/or long-term effects on the solution of taking the new direction, or does the subject simply jump into the new approach?

T4: What are the local and global effects on the solution of the presence or absence of assessment as a new path is embarked upon? Is the action there appropriate or necessary?

This method of analysis highlighted further categorization of what self-regulation means in the problem-solving behavior of Calculus students and its effect on mathematical efficacy.

### Data Sample

Primarily, two classes of Calculus and Advanced Calculus were observed for two semesters at a leading British University. Working closely with the students in problem-solving classes certain students were chosen for their ability to think-aloud well and their problem-solving behavior. This said, the students chosen were still of varying ability and gender. We then completed a pilot study with three groups of 2 to 3 students per group to explore the existence of various metacognitive behaviors. Over the course of the following year, these three groups met periodically through two stages of the main data collection. Both sessions involved solving problems from the integral calculus. They had covered the relevant material that same semester yet they had not seen the problems previously. Examples of the problems include:

#### *Problem 1*

$$\text{Evaluate } \iint_R x^2 \sin(x^4 + 2x^2y^2 + y^4) d(x, y)$$

where  $R$  is the region satisfying  $x^2 + y^2 \leq 1$  and  $y \geq 0$ .

#### *Problem 2*

$$\int_0^1 dx \int_x^{x^{1/3}} \sqrt{1 - y^4} dy$$

These questions call for a degree of spatial awareness and flexibility, manipulation of co-ordinate systems and the geometric consequences, and retrieval of algorithmic and algebraic techniques from other areas of the Calculus.

Stage 1 of the empirical work comprised of two exploratory studies. These studies illuminated certain characteristics of metacognitive thinking which affected their problem-solving skills and led to the development and refinement of the four main

items of self-regulatory thinking - one of which we report on now. Stage 2 aimed at verifying and further developing the four main areas of self-regulatory thinking evident in stage 1. The observer intervened in stage 1 to assist in thinking-aloud which was in direct opposition to Schoenfeld's methodology. In stage II, a strict interventionist agenda was set up to direct the line of inquiry. In both stages an interventionist analysis was conducted to observe any bias in contriving the reported metacognitive behavior. Limitations of this report prevent us from detailing this method but it is incorporated in our analysis.

### **Analysis of Reflective Thinking**

Throughout the study it was evident that the students' metacognitive behavior in the form of self-regulation was intimately bound up with the mathematics.

Three types of reflection describe this behavior:

1. Forward-reflection,
2. Backward-reflection,
3. A-temporal reflection

The first refers to looking forward into the solution and how it might develop; predicting outcomes or expecting changes based upon the solution so far or through experience. The second refers to checking and verifying the algebraic and geometric structure in the solution so far; why these were chosen and how they have an affect on how the solution might develop. The third is line-by line and on-the-fly checking often performed without close regard but nevertheless contributing to the coherence or development of the solution. This latter one is harder to distinguish yet more understood as part of problem-solving. The former two are what we particularly concentrate on in our analysis.

It is evident that each type of reflection is largely guided by the form and shape of the various mathematical signs and symbols in the students' problem-solving domain.

In general, the students involved in the study often only examine the variables of integration when they are substituted for another rectangular variable or converted into polars. Reflection on such a change of variable is often in the form of backward reflection. The students reflect upon the suitability of the change of variable with respect to simplification of the algebra. The change is not a function of the theoretical suitability or effectiveness of the new variable, which is a form of effective forward reflection. This has repercussions on the limits of integration that were formulated through the region of integration.

It is evident in the students' behavior that changing the order of integration could minimize the levels of difficulty in the algebra (i.e. forward reflection) but the theoretical implications of such actions again are often not acknowledged.

Figure 1

In general, it is reflection on the shape of a region and the form of the algebra that leads to a change in the variables used. We offer extracts of various pieces of work where two average students are working on the first and second problem above.

Following a Schoenfeld protocol analysis we constructed time-line diagrams for each of our sessions. One of the groups completing problem 1 is given in figure 1. It is evident that the students' work followed many periods of transition (grey block areas) and circulated through many plans. We performed the same analysis for expert problem-solvers (Mathematics Professors at the same university), and what is comparative with their solution and the student's work at the meta-level is the extended use of analysis time.

Our protocol analysis has highlighted particular aspects of their work (albeit ineffective) which relate to their reflective thinking as a self-regulatory thought mechanism through analysis of the verbalizations of the student with their written work. This was intimately bound up with the mathematics they were engaged with and their comprehension of the various concepts, algebraic and geometric techniques that they struggled with.

We offer one example of the verbal data which highlights the students' reflective behavior in attempting example 1. Backward reflection on the circularity of the region  $R: x^2 + y^2 < 1$ , already drawn in their work (see figure 2), leads one of the students to change the rectangular variables to polars (i.e. cylindrical):

G: Erm I think we might have to change the er ... the variables to polars because er ...

S: Why do you say that?

Evaluate

$$\iint_R x^2 \sin(x^4 + 2x^2 y^2 + y^4) d(x,y)$$

where  $R$  is the region satisfying  $x^2 + y^2 \leq 1$  and  $y \geq 0$ .

$x = r \cos \theta$   $x^2 = r^2 \cos^2 \theta$  (1)  
 $y = r \sin \theta$   $y^2 = r^2 \sin^2 \theta$  (2)

$$x^2 + y^2 = r^2 (\cos^2 \theta + \sin^2 \theta) = r^2$$

in polars  $r^2 \leq 1$

 This region. find limits.

 (x<sup>2</sup> + y<sup>2</sup>)<sup>2</sup>

Look at original integral  
 $\int \dots (x^4 + 2x^2 y^2 + y^4)$   
 $(x^4 + y^4) + 2x^2 y^2$

Now (1) and (2):  $[(r^2 \cos^2 \theta)^2 + (r^2 \sin^2 \theta)^2] + 2(r^2 \cos^2 \theta \cdot r^2 \sin^2 \theta)$

$r^4 (\cos^4 \theta + \sin^4 \theta + 2 \cos^2 \theta \sin^2 \theta)$

$r^4 (\cos^4 \theta + \sin^4 \theta + 2 \cos^2 \theta \sin^2 \theta)$

$(r^2 \cos^2 \theta)^2 + (r^2 \sin^2 \theta)^2 + 2r^2 (\cos^2 \theta \cdot \sin^2 \theta)$

$\cos^2 \theta = \frac{1 + \cos 2\theta}{2}$   
 $\sin^2 \theta = \frac{1 - \cos 2\theta}{2}$

Figure 2.

G: Well because we're doing a double integral we going to end up with a volume over that the base .. which is  $x^2 + y^2$ .. and because it's less than or equal to 1 it's the disc not a circle so .. we've got a circle and everything inside of it so you've got like this base .. horizontal and you're going to be evaluating up in the air and you need to find what the limits are .. and polars are a bit easier to work with.

S: Why would they be easier? What would they convey? What would that expression be in polars? The  $x^2 + y^2$ ...?

G: Erm .. I'll write it down. Because it's  $x = ... r \cos q$ , I think .... y's  $r \sin$ . [Pause]

G: Right so that's  $r^2$  ... should have known that ... but it's in polars so you've got  $r^2$  less that equal to 1.

S: So that region has led you to say polars?

G: Yeah.

[G - Student S - Researcher]

Having completed this stage, the students then thought about the implications of their substitution on the solution.

The region of integration plays an important role in determining the limits of integration and suitable methods of integration. It is evident in many of the students' work that the provision of a diagram for the region of integration is useful to these effects, but it is only effective if a theoretical understanding of the region is evident.

Reflection on the region often concerns the method of 'slicing', either by using washers or discs, in single integration. In double integration, it affects the construction of the limits of integration. It is not evident in their reflective behavior, though, by what means the region could effectively establish a suitable procedure of integration that would decrease difficulty in algebraic manipulation. Whilst reflection on the integrand in geometrical terms is not evident (i.e. as a surface  $w = f(x, y)$ , say, in double integration, or a hypersurface  $w = f(x, y, z)$  in 4 space for triple integration) this behavior does not have any direct effects on their problem-solving processes. Reflection on the form and shape of the integrand and its algebraic construction is evident and this affects the choice of method, and the algebraic manipulation of it. In the example below, G & D (students) are attempting to solve the integral in problem 2:

S: Why can't you integrate it?

D: Well ... its in terms of y's?

S: Yeh.

D: Because .. I can't remember why but the function is er ... erm ...

[Pause]

G: Is it just because it's improper because it's y to the 4. I know you can do it if it's like something squared .. minus something squared square rooted.

S: Yes you saw that last term .. last semester, didn't you?

D: Yeh.

G: You've got to make a substitution with the y to the 4 .. you've got to substitute like er  $z = y^2$ . So like you then you got  $1 - z^2$ .

D: Which is  $1 - z^2$  which equals er .. a standard integral, which is the back of the book. which I can't remember what it is?

The students then debate whether to change the order of integration and thus integrate the integrand with respect to  $x$  first rather than  $y$ . This, of course, would be the most suitable method, as long as suitable changes in limits are made.

In other examples the acknowledgement of oddness/evenness or symmetry in the integrand lead students to effectively reduce the levels of algebra in the integration procedures.

Reflection on the limits of integration seems only evident in the substitution of them. Even then, reflection is minimal. Furthermore, line-by-line reflection is not evident which results in algebraic difficulties and mistakes.

The shape and form of the algebra is often the driving force behind the organization and retrieval of procedural tools, but the functionality and efficiency of these tools is poorly reflected upon. These tools are both algebraic and algorithmic, and include for example, methods of anti-differentiation, trigonometric substitution, and the substitution of trigonometric identities.

### **Conclusion: Links to Practice**

In general, reflection on the form and shape of the algebra lead to a variety of conceptual and procedural thinking. In conclusion, backward reflection caused the manipulation of algebra and the interpretation and reconstruction of geometric objects, which were part of the Calculus problem. Such behavior was conducted to varying degrees of efficiency. Progress occurred when reflection was also in a forward sense that looked critically at the choices made and understanding the theoretical implications (in terms of the Calculus) of their implementation. In addition, reflection is supported by the implementation and integration of the three other main self-regulatory behaviors (organization, monitoring and extraction) highlighted earlier.

This work has shaped a theoretical perspective to observe how self-regulatory thinking is a function of the mathematics being investigated, particularly the Calculus, and our present line of inquiry is exploring how these insights help inform pedagogy and how they might be implemented.

Key to the current discussion about the mathematics education of today's youth are concerns about the mathematical knowledge and background of secondary school mathematics teachers (CBMS, 2001). Current research suggests that teachers with robust understandings of the mathematics they teach are capable of teaching for understanding. For example, Lloyd and Wilson's (1998) case study of one teacher suggested that "teachers' comprehensive and well-organized conceptions contribute to instruction characterized by emphases on conceptual connections, powerful representations, and meaningful discussions" (p. 270). Current research (Manouchehri & Goodman, 2000) also suggests that teachers without such robust and connected understandings may be unable to capitalize on opportunities to enrich the discussion of mathematics in their classrooms.

Although deep understanding of mathematics is not all that is needed for teachers to teach for conceptual understanding and mathematical meaning (Ebby, 2000; Wilson, 1994;), such understanding does seem to be central to teacher's effectiveness, and so it is important to understand the nature of prospective secondary teachers' understandings.

Central to the organization of mathematics is the concept of function (Bidwell & Clason, 1970; MacLane, 1986), a notoriously difficult concept for students (Dreyfus, 1990; Markovits, Eylon, & Bruckheimer, 1988; Yerushalmy & Schwartz, 1993). The word "function" often evokes the notion of  $\mathbb{R}$  to  $\mathbb{R}$  functions, and research on understanding of function focuses on  $\mathbb{R}$  to  $\mathbb{R}$  functions. With the renewed emphasis on mathematical modeling in new school curricula and access to interactive three-dimensional environments, however, multivariate functions command increased attention. One can examine the depth of student understanding of the function concept by examining the transferability of this idea from the familiar, real-valued functions of one variable, to

the unfamiliar, real-valued or vector-valued functions of several variables. As Yerushalmy (1997) suggested, as students deal with multivariate functions and related new notation systems, new notions of dependency (coordination of multiple dependencies), and the notion of families of curves as a single object, their concept of function is stretched. Our study characterized prospective secondary mathematics teachers' understandings of function as seen through their work in multivariate settings.

### **The Study**

This study examined the mathematical understandings of prospective secondary mathematics teachers of the concept of function as shown through their work in the context of their participation in a course in which one focus was multivariate functions. The context was an elective mathematics/mathematics-education course at a large university. For two consecutive semesters, two mathematics education researchers, one research mathematician, and several graduate students designed, implemented and studied student understanding in the context of students' work within the courses. Although the two courses consisted of different material, both courses adopted as a central focus functions of several variables. This report will focus on the data gathered during the second of these two courses.

### **The Course**

The course consisted of 15 three-hour class sessions each semester. One of the major foci of the course was to develop students' understandings of function. In particular, students studied a range of manifestations of function, including multivariate functions, transformations, and contextually embedded functions. In this paper, we will focus on their work with multivariate functions. Students studied multivariate functions through examination of graphical, analytical and contextual/data and model-driven representations of functions of several variables. During the course, we engaged students in investigating functions of several variables using electronic technologies (Geometer's Sketchpad, Mathematica, DPGraph, TI-92+, etc.), manipulatives (Zometool and DoodleDome), and office-supply materials. Students studied the decomposition of graphs of functions of two variables into curves obtained by slicing the graphs with 'standard' planes (those parallel to the coordinate planes). Students also studied the construction of the entire graphs using a few such slice curves. Students were called upon to make connections between graphical and analytic representations of such functions.

A feature of our approach to teaching about multivariate functions was to help students reduce the study of multivariate functions to the study of a collection of functions of one variable obtained by fixing a number of the variables at constant values. Students who learn to view functions of two variables this way would presumably be able then to use their understanding of graphs of real-valued functions of one real variable to identify the resulting curve. Generally, the graph of a real-valued function

of two variables is a surface. Geometrically, fixing one variable at a constant value corresponds to slicing the surface with a plane. The intersection of the plane and the surface is then a curve in that plane. By fixing the variable at different constant values, one gets different planes and hence a family of slice curves. One could also vary which variable to hold constant, producing a different family of slices the collection of which also describes the surface. If the students could understand the family of curves so obtained, it was our assumption that they would then be able to work on the problem of trying to understand how those curves could be assembled into the original surface. They also could work on understanding how attributes of the slice curves determine attributes of the surface, and of the original function in question. Students in these courses worked on the graphical to analytical (given the graphs, work on developing analytical formulas) and the analytical to graphical (given the analytical formulas, work on developing graphs) implementations of these strategies.

### **Data Sources**

The study in which this investigation lies relies on four data sources: videotapes of whole class sessions, videotapes and annotated transcripts of small group work in class (during the Fall class only), videotapes and annotated transcripts of individual interviews, and copies of out-of-class assignments (used primarily for planning of subsequent class sessions). The Fall 2001 data included beginning-of-semester, mid-semester, and end-of-semester interviews with eight students. Each interview lasted 60 to 90 minutes. The whole class sessions, small group work and individual interviews provide different insights into students' understanding. Our primary analysis for this paper entailed examination of the interview data, corroborated by the data from the other sources.

Whole group discussions were based on inquiry and exploration, and shifted the authority to the student. This enabled us to examine evidence of understanding as seen in students' reactions to other groups' conjectures or conclusions, and in the ways in which students provided what they saw to be convincing arguments in a group setting.

Small group discussions were a regular part of the class sessions. Each group generated results that each member was responsible for being able to explain/support. Although the instructors sometimes posed clarifying and extending questions to individual groups as they watched the group's work, for the most part, the groups worked without interference. This enabled us to examine evidence of understanding as seen in the ways in which the groups approached and solved problems and in reactions of group members to other students' ideas and reactions to other groups' conclusions/conjectures as well as in interaction with other students and other groups.

Individual interviews provided us with evidence of the arguments that were convincing to the student him/herself. They provided us with the opportunity to probe and examine students' understandings more deeply than what is possible in small group

and whole group settings. We could observe what students did as they generated ideas on their own and reacted to mathematical ideas and situations. Throughout the course, students encountered a range of examples of functions. It was through these experiences that we expected students to develop a broad and connected concept of function that would generalize beyond an ability to work with a prototypical  $\mathbb{R}$  to  $\mathbb{R}$  function. From our perspective, a function is a mapping from one set (the domain) to another set (sometimes called the codomain) so that each element of the domain is assigned to one well-defined element of the codomain. A relation is a mapping from one set (the domain) to another set (sometimes called the codomain) without the restriction that each element of the domain is assigned to exactly one element of the codomain. The domain elements are called inputs and an element of the codomain corresponding to such an input is called an output. The set of inputs and the set of outputs need not be confined to numerical values. The set of output “values” associated with the domain is called the range of the function, and may be a proper subset of the codomain. The vertical line test is a strategy for ruling out particular relations as functions. Families of functions are functions with a common characteristic, frequently with a function rule that has a common form with parameters whose values vary among different members of the family. The meanings of fixed points, maxima and minima, domain, and range all draw on the general meaning of function as a mapping.

Through the interviews, we sought to understand students’ understandings of the function concept. We asked questions about function and related ideas in a range of contexts with which students were expected to have varying familiarity. In this paper, we will focus on student responses to questions asked during the third interview.

The third interview was conducted at the end of the semester. During the third interview, students were asked about their concept of function with questions like:

- What is a function?
- Can you give an example of a function?
- Here is a common definition of function: A function is a set of ordered pairs no two of which have the same first element. How can you tell whether something is a function?
- Can you use the vertical line test to tell whether the graph I am showing you [graphs of  $x = 9y^2 + 36$  and  $y = 9x^2 + 36$  are shown] is that of a function?
- Some functions have what we call fixed points. Can you tell me what a fixed point is?
- Here is a common definition of a fixed point: If  $x$  is an input value for which  $f(x) = x$ , then  $x$  is called a fixed point of  $f$ . Can you tell me whether the function  $f(x) = x^2 - 3x - 12$  has any fixed points?

Portions of students’ understandings of the function concept were disclosed in

their work with functions of two variables. During the interview, three particular settings were provided as occasions for the students to talk about functions of two variables. The first setting was an article appearing in a nationally distributed newspaper reporting a new formula for the wind chill factor. The article had several typographical errors. The first typographical error was the omission in the function rule of one of the variables; the new wind chill factor was reported as a function rule with only the air temperature (and not the wind speed) as input. The rule appearing in the article was " $WC(^{\circ}F) = 35.74 + 0.6215T - 35.75(V^{0.16}) + 0.4275T(V^{0.16})$ ", instead of the correct rule, " $WC(^{\circ}F) = 35.74 + 0.6215T - 35.75(V^{0.16}) + 0.4275T(V^{0.16})$ ". The second typographical error was the omission of information from a graph related to the function rule. The graph was a two-dimensional slice of the three dimensional graph, but no information was given identifying which particular slice was the one that was shown. Students were asked to make sense of the article and its representations of the function rule. The second setting was an  $\mathbb{R}^2$  to  $\mathbb{R}^2$  function, the transformation of points in the plane to other points in the plane by a mapping 45 degrees counterclockwise about a given point C. Students were asked whether the rotation was a function, and why. They were asked to argue from a given definition of fixed point whether the rotation had any fixed points. Third, the students were given a dynamic graph (one that rotated) of the function,  $f(x,y) = 5xy + 4x + 4y$ , with the function rule appearing on the graph. One frame of the rotating graph animation is shown in Figure 1. Students were asked questions like the following about this function of two variables: Is that relationship a function? Why? Can you use the definition of function to show that the relation is or is not a function. Does this relation (or function, if they decide it is a function) have any fixed points? Can you use the definition of fixed point to convince me that (insert their conclusion)?

Figure 1. One frame of a dynamic graph (one that rotated) of the function,  $f(x,y) = 5xy + 4x + 4y$

**Data Collection Methods/ Analysis Methods**

In all three settings we video-taped and audio-taped to capture students' verbal statements and written work, and we directly captured the results of their work when using computer algebra systems (CAS) and dynamic geometry software using screen-capture technology (scan converters, TI Presenters).

Our ongoing analysis began with weekly reviews of the class sessions. We identified evidence related to understanding of key mathematical ideas, and reviewed them in planning for subsequent lessons and data collection. From annotated transcripts of interviews and small group work, we identified excerpts that involve functions of several variables. We are in the process of building models of students' understandings of functions, particularly as seen through functions of several variables. In building these models we are describing the nature of understanding of functions of several variables as shown in different contexts (e.g., dynamic three-dimensional graphs, symbolic representations of real world quantitative relationships).

**Results**

Based on the data we had gathered throughout the course, we made the following general observations:

- The prospective teachers with whom we have worked at first found the concept of multivariate functions difficult in spite of having successfully completed courses in multivariate calculus. They especially found it difficult to visualize graphs of functions of two variables. By the end of the course, many of them grew more comfortable with graphical representations and contexts representable by functions of two variables.
- There was some indication in our data that slicing planes enabled students to modestly improve their understanding of analytic/algebraic formulas for functions of several variables.
- At the end of the semester they had tools and strategies they could use to examine and study functions of several variables in an applied setting described in a current newspaper article.
- Students' sensitivity grew to the ways in which functions of several variables can describe real-world situations.

Several of the interview questions were particularly fruitful in revealing student understandings of function in that they suggested the nature and limits of students' understandings of the function concept. In the remainder of this paper we will present observations about the mathematical understandings of three of the students in our study (Bob, Ned, and Violet). We have selected these students in order to present a range of understandings of function among students in the same class.

### Students' Approaches to New Concepts as Seen in Their Work with Functions, Particularly Multivariate Functions

Students' approaches to understanding new concepts are revealed through their work with new ideas about functions, including functions of two variables. For example, Violet frequently confined her reasoning to the information that was currently in front of her. When presented with the newspaper article about the wind chill situation, she frequently used the empirical data presented in the article as her primary authority rather than reasoning from the function rule that was given. It was the fact that the article refers to the wind speed and air temperature being measured and used in the new wind chill formula that alerted Violet to the need for two variables in the formula. While she confined her reasoning to the given, she used the given information carefully and accurately. When given the graph appearing in the article, she immediately remarked that the equations in the graph differed from those in the article. She quickly determined that the graph depicted the wind chill when the temperature is held constant, and she recognized that the air temperature was 5 degrees from reading the website graph. She was careful not to reason beyond the information she was given, and this tendency was sometimes coupled with a tendency not to reason across representations. In the dynamic graph situation, she hesitated to make conclusions about values that exceeded the limits of the window provided, in spite of the fact that she was also given the function rule for the graph.

Violet's reasoning about function seemed to be in a transition between rote understanding and sense-making. She displayed almost a stimulus-response reaction when asked to describe slope, by immediately responding "rise over run" without specifying what the "rise" and "run" represented. A similar phenomenon occurred when she was faced with a quadratic function rule; her immediate reaction was, "... my first thought was to factor it." Violet was able to reason using critically conceptual prototypes to clarify her own concepts. She recalled somewhat vaguely that one could determine that something was not a function by using either a vertical or a horizontal line test, and reasoned from prototypes to decide which rule made sense. She used rich prototypes to clarify her understanding of this and other concepts (domain and range; whether a function needed to be one-to-one). Whereas Violet was able to clarify her understandings by consulting prototypes, her reliance on algebra conventions sometimes muddled her understanding. For example, with her reliance on the convention that  $x$  is an input variable and its associated "vertical line test," she was not able to view the graph of  $x = 9y^2 + 36$  as a function (with  $x$  as a function of  $y$ ). Violet did not reason from definitions even when they were supplied, but rather tried to fit these definitions into her own concepts. For example, when she was given a definition for function, "A function is a set of ordered pairs no two of which have the same first element," she debated the definition by thinking about the vertical line test and some critically conceptual examples of functions on which she had learned to rely.

**Students' Understandings of Function as Seen in Their Work with Multivariate Functions**

Students' understanding of function is revealed through evidence of their understanding of functions of two variables. Ned seems to understand function as a mapping from a given set to another set, and displays that generalized understanding in a range of encounters with  $\mathbb{R}$  to  $\mathbb{R}$  functions and even with geometric transformations (types of  $\mathbb{R}^2$  to  $\mathbb{R}^2$  functions). He had difficulty, however, in applying the definition of function to a graph of  $f$  with rule  $f(x,y) = 5xy + 4x + 4y$  or  $f((x,y)) = 5xy + 4x + 4y$ . He seemed to need to think of two numerical inputs for the function instead of thinking of the input as an ordered pair of values,  $(x,y)$ . Ned may have been uncomfortable with treating entities other than numerical values as input for functions.

It's just that it seems, it just sort of seems to follow that, you know, I have this idea of what a function is in two-dimensional space. So then I go to three-dimensional space, I have an extra value in my ordered set. Now I have an order of triples instead of ordered pairs. I'm just sort of following along with that function and just making a logical step in saying that. And they can't have the...the first two elements can't be the same in order for a three-dimensional figure to be a function.

This example of thinking of input as numerical was unusual for Ned. Bob, on the other hand, seemed almost always to think about input for functions as having to be real numbers, thus inhibiting his transition to the idea of fixed points for a function with a three-dimensional graph. After seeing the definition of fixed point, Bob changed his way of approaching the idea of fixed points and came to an understanding that a fixed point is an input with an equal corresponding output. However, his only way of deciding on whether an input value was a fixed point or not was to calculate and compare numerical inputs and outputs, and he was unable to determine fixed points symbolically. Although Bob's numerical bent served him well in his work with  $\mathbb{R}$  to  $\mathbb{R}$  functions, it served as a cognitive obstacle when Bob needed to generalize to other types of functions.

Unlike Bob's and Violet's understandings, Ned's understanding of function was flexible enough that he did not need to rely on a single strategy for determining whether a relation was a function. Bob and Violet relied on the vertical line test and were able to apply it to  $\mathbb{R}$  to  $\mathbb{R}$  functions. When they were asked how it might apply to a function of two variables, however, the fragility of their understanding was uncovered. Bob struggled to construct a way to apply the vertical line test in three dimensions.

Bob            I'm trying to think of ...how you're not going to get two outputs for each input. But you do have two outputs here for the same...I don't know, whatever value that is. ...You're getting two outputs. Maybe you're not gonna get three outputs when it changes to that.

Interviewer: Why three?

Bob: Because now it's a function of two variables. Because these two points [pointing to two points on the graph of the surface in Figure 1 with his small and index fingers] are definitely the same  $z$ . And so are these two and so are these two and yada yada. Umm... Or wait, no, that's... They wouldn't go this way. I want to look at it this way. I want to look at it this way. Yeah, well, I guess you could do the same test [moving his small finger from up to down].

Interviewer: When you say the same test...

Bob: Maybe vertical line test? I don't...I've never done that three-dimensional. I haven't seen much three- stuff. ... And you'd only get one value. And I'm trying to think of a graph, if I've ever seen it where you get more than one, but I don't think so. Hm-mm. I mean at zero you'd only get one value for  $z$ ...for each  $x$   $y$ , your values for  $x$  and  $y$ .

Interviewer: Okay. So if that test held true, then you're saying this would...that would be an argument that this represents a function.

Bob: I would say. Okay.

Violet, on the other hand was somewhat intrepid in venturing into new territory with her concept of the vertical line test. In making the transition between working with functions of one variable and functions of two variables, she noticed the grid lines on the graph of  $f(x,y) = 5xy + 4x + 4y$  and decided that this was a function because each of these lines passed the vertical line test. Her conclusion seemed more based in modeling the procedure she had learned than in applying the concept.

### Students' Understandings of Multivariate Functions

Each of the students found a way to talk about multivariate functions. It turned out that a hands-on activity in which we had groups produce a model of a graph of a multivariate function in class was a powerful cognitive device. Each student drew on his experience in this activity in a different way. Bob thought about multivariate functions by evaluating slices of the surface numerically. Violet called upon the model which was created in class and talked about "frames" (her name for slices). Ned seemed to have the most robust understanding, tailoring the model produced in class:

If I were to plot it all on an  $X$   $Y$  plane, I would just get a whole bunch of graphs like, you know, ... And they're just gonna get this whole range of lines, just you know an infinite really amount of lines. Well, you could do it, you know, like we did it in class where we used the three dimensional, the "Office Max" model or whatever, ...And you could say that we're gonna call this axis. We're gonna have this be the changing  $T$  along this axis [draws hash marks along axes]. And you could graph, you know, and you would have one single graph that looks like that [picks up paper with graph of a slice

and holds over each hash mark one at a time] and you could plot it, you know, and you could do the overhead thing and you would get some sort of...[takes hand and moves from "ball" of graph curving down following axis with hash marks] you know, as  $T$  increased and decreased you would get some sort of curve and, you know... If this is this curve by my hand, you know, you would get something like this as  $T$  increases and decreases [uses hand to trace surface in air] I believe as some sort of wave looking guy or something. I don't know. But, yeah, to really get a good look at that, you should have some sort of three-dimensional thing.

### Conclusions

In spite of their having completed a multivariate calculus course, students had entered our class with little ownership of their understanding of multivariate functions. As we investigated students' understandings of multivariate functions, we realized that understanding their understanding was a two-way street. As they encountered functions of two variables in our class, we witnessed their approaches to generalizing their mathematical understandings. Moreover, their work with function concepts in the context of multivariate functions revealed much about their understanding of function. Our analysis has just begun. It will continue with the examination of other data about these students and with data about other students in the class. We expect that our work will draw us closer to building viable models not only of how prospective secondary mathematics teachers come to understand new mathematics but of how they understand the concept of multivariate function.

## STUDENT STRATEGIES FOR REINVENTING LINES OF EIGENVECTORS<sup>1</sup>

Michael Keynes  
Purdue University Calumet  
keynes@calumet.purdue.edu

Chris Rasmussen  
Purdue University Calumet  
raz@calumet.purdue.edu

The purpose of this research report is to delineate a student invented method for locating lines of eigenvectors associated with systems of two first order linear ordinary differential equations with constant coefficients. Our research has both pragmatic and theoretical significance. Pragmatically, we are using the results of our findings to revise a sequence of instructional tasks and to inform our instructional decision making. Theoretically, we are using these results to inform the creation of a conceptual framework for how students' develop important mathematical ideas in differential equations. The work reported here lays a foundation for both these endeavors.

### Introduction

Advances in technology and mathematicians' evolving interests in dynamical systems are currently prompting changes to the introductory course in differential equations. Traditional approaches in differential equations emphasize analytic techniques for finding closed form expressions for solutions whereas current reform efforts are emphasizing graphical and numerical approaches for analyzing and understanding the behavior of solutions. In the treatment of systems of differential equations, the use of phase plane analyses for describing and predicting solutions is receiving increased attention (Kallaher, 1999). The little existing research related to students learning of systems of differential equations (Artigue, 1992; Rasmussen, 2001; Trigueros, 2000) indicates a variety of difficulties with basic ideas and methods of analysis. The research reported here complements this small but growing body of research in student learning by highlighting students' intellectual achievements rather than their shortcomings.

The purpose of this research is twofold. First, we wish to document a student-invented approach for locating solutions that, when viewed in the phase plane, fall along straight lines. From a mathematical point of view, straight-line solutions are determined by the eigenvalues and eigenvectors for the  $2 \times 2$  matrix corresponding to the system of differential equations. Typical approaches for finding the closed-form solution for these straight line solutions employ techniques from linear algebra where students first find eigenvalues, then find the corresponding eigenvectors, and then form the analytic solution. Although students can often find eigenvalues and eigenvectors, the meanings of these mathematical ideas tend not to be well understood. Second, we view the research reported here as foundational because our analysis focuses on student invented methods for first finding eigenvectors and then eigenvalues (a reversal of the typical order) through their interest in locating straight-line solutions. The

instructional design of the materials is based on students' mathematical goals rather than a top-down approach. As such, we document students' conceptual development of straight-line solutions as they reinvent the ideas of eigenvectors and eigenvalues from their own sense-making.

In our work with students, we treat graphs of solutions in the phase plane as inscriptions that potentially emerge out of students' reasoning. This perspective builds on recent theoretical advances in symbolizing (Cobb, Yackel, & McClain, 2000) and differs from typical reform-oriented approaches in differential equations. For example, Smith (1998) posits that after drawing a slope field for a single differential equation, "the meaning of a solution is then clear: We seek a function whose graph 'fits' the slope field" (p. 12). We start from the premise that meaning is not inherent in an inscription like a graph or vector field, but rather grows out of students' interactions and experiences with such inscriptions (Blumer, 1969).

### Methodology

Our methodological approach follows the classroom teaching experiment as described by Cobb (2000). In brief, this approach involves the development of a tentative and revisable set of instructional activities, classroom enactment of these activities with ongoing revision of the activities based on day to day analysis of classroom events, and retrospective analysis of all data sources once the experiment is completed. Data sources include videorecordings of every class session, videorecorded interviews with students, copies of all written work, instructor's journal, researcher fieldnotes, and audiorecordings of project meetings. Our instructional planning about students' conceptual development was informed by research on students' learning about rate of change in general and about differential equations in particular (Thompson, 1994; Rasmussen, 1999, 2001) and by our understandings of the Realistic Mathematics Education instructional design theory (Gravemeijer, 1999). The method of data analysis follows the constant comparison method outlined by Glaser and Strauss (1967) and elaborated by Cobb and Whitenack (1996) for classroom teaching experiments. We carried out our research in two different classrooms. In one classroom, we conducted a 15-week modified classroom teaching experiment where we collected copies of student work, held weekly project meetings, and keep field notes of classroom events. In another classroom, we conducted a 15-week classroom teaching experiment where we also videotaped each class session and conducted interviews with students.

As RME instructional design is founded on student motivations and understandings, listening to student questions and ideas becomes a critical tool to the development of curricular materials. The motivation for choosing this particular instructional sequence was based on questions students had from previous semesters. A particular student comment during a class when small groups were investigating how vector fields change as a parameter changed in the differential equations using technology. A student had been looking at the vector field associated with a linear system of differ-

ential equations which had straight-line solutions. The vector field for a system with a straight-line solution, or eigensolution, would appear to have a collection of vectors lying on a line through the origin, where each vector is parallel to the line (see figure 2 below for an example). Although the student hadn't had any experience with analytic forms of the straight-line solutions, he had been perplexed as to why the vector field seemed to have a "line" running through the middle of it. Traditionally, these lines are determined analytically by finding the eigenvectors associated with the  $2 \times 2$  matrix associated with the system. This student's question was used as a motivation for a class investigation into whether there was a straight line in the vector field and if so, which line was it. To the students' surprise, by developing analytic techniques, they found a second straight-line solution that wasn't as visibly clear as the previous one. This created questions for students to study its implication for solutions to the system, and its use for modeling graphical and analytic solutions to the system. In addition, the ideas and concepts that were used answer the students question for this specific system and could be used to analyze other systems. As a result, the instructional sequence was modified to reflect student questions and address eigenvectors first and then develop eigenvalues.

### Results

Students in these differential equation classes were primarily engineering students, although there were a few mathematics and science majors, mostly in either their sophomore or junior year. During the videotaped class in this study, students were analyzing a system of differential equations modeling the motion of a mass on the end of a spring with friction, as seen in figure 1.

The classroom topics covered up to this point in the course included detailed investigations of first-order differential equations as well as some qualitative experiences with non-linear systems of differential equations. This included looking at solutions as three dimensional curves and as pairs of functions of time, discussions of the

Figure 1. Diagram of the spring-mass system.

phase plane and how it related to the functions, as well as qualitative and quantitative aspects of equilibrium solutions.

To investigate a specific spring-mass problem with variable kinetic friction, we had chosen the mass to be 1 and the spring constant to be 2. As a result, these system of differential equations were

$$\begin{aligned}\frac{dx}{dt} &= y \\ \frac{dy}{dt} &= -2x - by\end{aligned}$$

where  $x$  represents the position of the spring mass relative to the equilibrium point,  $y$  represents the velocity of the mass, and  $b$  is the coefficient of friction. Before doing any analytic or graphical investigations of these equations, students had conjectured that the possible motions of the mass were either oscillations with a fixed amplitude if  $b = 0$ , or oscillations with a decreasing amplitude over time if  $b > 0$ . Students drew diagrams of what curves in the phase plane would be for each of their physical predictions. Rather than introducing students to analytic methods for obtaining solutions to differential equations, we had students use technology to graph the different possible vector fields in the phase plane as the friction coefficient varied. More importantly, the technology we used only plotted the vector field, it did not actually plot out graphs of solutions in the phase plane. It did, however, allow students to interactively move a point with its associated vector about in the plane and allowed students to dynamically change the vector field for different amounts of friction. They confirmed that both conjectured situations actually did arise for particular  $b$  values. Using the program NuCalc®, students plotted the following vector field when  $b = 3$  as seen in figure 2.

Figure 2. Vector field associated with the spring-mass system.

This is an over-damped oscillator, meaning that not only does the system have real-valued eigenvalues and eigenvectors, but that the mass will not cross the point  $x = 0$  after having initially been displaced from it.

Students were asked to describe the motion of the mass at  $b = 3$  to see if it matched what they had predicted. Students weren't sure as to whether the mass was oscillating, as they had previously predicted, or whether the behavior was different. To help facilitate classroom conversation, the image of the vector field on the computer screen was projected up at the front of the room. Student A made the following argument that the motion was different.

Student A: I mean, if it was just one circle, like when  $[b]$  was 0, then these would all link up [pointing to the vectors in the third quadrant], you know what I mean. But you can see these [pointing to the second quadrant] are way different, uh, uh, slopes than over here [pointing to the third quadrant], so it's not going to work that way. It almost seems like it's going to come up almost like that [draws the path on image of the phase plane in the fourth quadrant with his finger seen in figure 3] and it will do the same over here. [draws the reflected path in the second quadrant seen in figure 3]

Figure 3. Student suggestions of possible paths in the vector field.

Student D: Like an eight?

Student A: It's not a total... Two arcs almost.

Student A used the inscription of the phase plane as a reasoning tool. Because the phase plane has particular characteristics, Student A noted that the vectors drawn in the plane do not match the vectors that would be necessary for simple harmonic motion as discussed before. There was no discussion as of yet as to how his conclusions related to the physical movement of the mass.

The class then discussed what the physical implications of such solution curves in the phase planes were. After establishing that for this friction coefficient, the mass would not oscillate, further discussion ensued in the classroom as to whether larger initial starting positions of they would actually oscillate rather than return to the origin. Student S argues that the straight line solution extends to infinity.

Student S: In this case, if you start here [points to approximately 1 on the x-axis], it should, you're not going to have a lot of velocity towards the equilibrium, so it'll go like this [makes a similar path to what student A did in figure 3, starting at  $x = 1$ ]. But here, if you start here, [points to about 5 on the x-axis] you're moving faster then you slow down... You can make a line out of [the arrows which directly to the origin], so how can it ever overshoot this line? So even if you started at fifteen, it'll all go like this [draws a similar path to what was shown before].

It is likely given the context of the conversation that Student S is coordinating the physical movement of the mass ("you're not doing to have a lot of velocity towards the equilibrium," "you're moving faster then you slow down") to inscriptions within the vector field and associated solutions (starting at places on the vector field and drawing out particular paths). For Student S, the vector field is a tool for reasoning, as he uses the vector field to describe physical phenomenon and makes a claim that oscillations can't occur because of aspects of this particular inscription.

As most of these students had some background in physics or engineering, the situation of a spring on a mass is one which is experientially real. We do not use this example to motivate the study of simple harmonic motion, but rather to capitalize on the students' familiarity with this phenomenon as a starting point for mathematical progression. Students were able to use their physical intuition to anticipate which motions for the mass should be possible and to translate the physical motions into inscriptions in the phase plane. When students are faced with solutions which are not one of the ones they had predicted, the investigation of the straight-line solutions becomes a question for them rather than one that is imposed on them.

The significance of the straight-line solution became clear as they were viewed as the limiting behavior of all solutions to the system of differential equations. We will refer to Student S's observation of a line that existed in the phase plane as the straight-line projection, as it is the projection of all straight-line solutions into the phase plane. Graphical interpretations then led to analytic investigations. What was the equation of the straight-line projection in the phase plane? Was this the only straight-line projection for this system of differential equations? How could you get the equation for the components of the straight-line solution? As students use graphical and physical interpretations as sense-making tools before using algebra, they are less distracted from the symbol manipulation that can distance them from the original meanings. Furthermore, the algebra expressions emerge as a way of expressing what has already been found and a means to adding insight to the analysis (Arcavi & Hadas, 2000).

Before continuing to address these questions, the class discussed what the graphical representation of the three dimensional curve of the triple  $(t, x, y)$  would look like. Although the fact that solutions to a system two differential equations could be represented by curves in three-space had been discussed in previous classes, a student offered that the graph of the solution should be a plane. His argument developed as follows:

Student C: I'm going to say that, because if you look at this plane, this is  $t = 0$  and it's a straight line. You can take any  $t$ , all the lines should be the same. So if we stack all the  $t$ 's on top of each other, you'll have a straight-line solution. So I'm going to say it's going to be a plane.

The plane student C referred to was perpendicular to the phase plane and intersected the phase plane exactly through the straight line projection, as seen in figure 4.

Figure 4. Student C's image of a straight-line solution.

Upon further discussion, student C told the class that he was using the fact that the system was autonomous, namely that the rate of change of both the position and the velocity didn't depend upon time. As a result, he believed that the straight line seen in the phase plane was just one of many straight lines, and all would be successively stacked on top of each other creating a plane. The class had previously studied autonomy of a single differential equation and student C was using analogies from this context to make sense of systems of differential equations. However, in class discussion, students brought up many points to respond Student C. First, they noted that while the rates of change can be determined solely by position and velocity, these quantities themselves vary with time. Furthermore, the fact that for each time there's one position and velocity implied that the solution would be a curve, rather than a plane. Students debated whether the curve would be straight or curved in three-space. They came to the conclusion that the graph would be curved since the vectors had

decreasing magnitude they approached the origin, and that this lead to the mass slowing down as it came closer to the equilibrium point.

This curriculum places emphasis on graphing of solutions of systems of two differential equations not only in the two-dimensional phase plane, but also in the full three dimensional system including time. The phase plane emerges as a result of students needs to express three-dimensional graphs in an efficiently but still maintain the essence of original graph. The connections between the phase plane and the three-dimensional graphs are traditionally difficult for students. The instructional activities allow students to use experientially real contexts to develop meaningful inscriptions and then use these inscriptions to analyze the contexts from which they emanated.

In the next class period, students developed a method for finding the slopes of the straight line projections in the phase plane. Many students had speculated that the line was  $y = -x$  and, using NuCalc, had checked particular components of vectors on the line to make sure that it agreed with their guess. The instructor asked if there was an analytic means that would work so that we didn't have to guess each time. A student offered the following method to developing an analytic means of finding equation of the straight-line projection: Since the line had to go through the origin as  $(0,0)$  is an equilibrium solution, we knew the straight-line projection would be of the form  $y=mx$ . Student A suggested using the fact that the slopes of the vectors and the slope of line they resided on were the same. Since the slope of the vectors could be determined by the ratio of the two rate of change equations, namely

$$\frac{\frac{dy}{dt}}{\frac{dx}{dt}} = \frac{-2x - 3y}{y} = m$$

by replacing  $y$  with  $mx$ , one could get an equation for the slope of the straight line by substitution, as seen below:

$$\frac{\frac{dy}{dt}}{\frac{dx}{dt}} = \frac{-2x - 3mx}{mx} = \frac{-2 - 3m}{m} = m$$

$$m^2 + 3m + 2 = 0$$

This yielded *two* solutions for the slope of the straight-line, namely  $-1$  and  $-2$ . While most had conjectured that the straight line projection with slope  $-1$ , the second one wasn't apparent and was a surprise to the students. The equations of lines students found are equivalent to the eigenvectors associated with the linear system, as any particular eigenvector is a representative from an equivalence class of a line.

Students began by analyzing the situation with regard to the physical characteristics of the spring mass system. For example, students looked at the effect of the

straight-line solution on the motion of the mass. Gravemeijer (1999) refers to this as referential activity, as it is based on interpretations based on the particular context. As students continued to develop their understandings of the straight-line solutions in that context, they were able to make statements and use formal mathematical reasoning independent of the context of the solution. Gravemeijer (1999) refers to this as general activity, where students begin to reflect collectively on the referential activity. For example, eventually the students explored relationships between  $x$  and  $y$  that were algebraic in nature rather than as the position and velocity of the mass on a spring. These analyses led students to develop not only techniques but understandings of straight-line solutions which transcended the particular situation first posed.

The development of the analytic form of straight-line solutions as parametrized curves  $(x(t), y(t))$  followed from graphical investigations of these curves using the program PPLANE authored by (Polking). This program allows one to enter in a system of differential equations, choose an initial condition, and examine the solution curve from many different angles and projections. By observing the two-dimensional graphs of  $x(t)$  versus  $t$  and  $y(t)$  versus  $t$ , as well as the three dimensional plots of both  $x(t)$  and  $y(t)$  versus  $t$ , students were able to conjecture that both  $x(t)$  and  $y(t)$  were of exponential type, namely that  $x(t) = C_1 e^{\lambda_1 t}$  and  $y(t) = C_2 e^{\lambda_2 t}$ . With this assumption in mind, students were asked what they could determine about the constants  $C_1$  and  $C_2$  as well as the exponential constants  $\lambda_1$  and  $\lambda_2$ . We assumed an initial condition of  $x(0) = 2$  and  $y(0) = -2$ .

To answer both of these questions, most students first began by looking at the graphs of  $x(t)$  and  $y(t)$  simultaneously using PPLANE, (as seen in figure 5). Students

Figure 5. Graphs from PPLANE program.

developed a number of ways to look at the relationship between the constants. One group plugged in  $t = 0$  and found that  $C_1$  and  $C_2$  were the initial conditions 2 and  $-2$ . Another group conjectured that the graphs were reflections across the  $t$ -axis of each other, so that this would be true for all  $t$ . When asked to explain why this was the case, a student offered that the relationship  $y = -x$  implied that  $y(t) = -x(t)$  for the straight-line solution. This meant that  $C_1 = -C_2$  for all initial conditions we chose for our straight line solution. Given that  $x(t)$  and  $y(t)$  were proportional, students also developed arguments that  $\lambda_1 = \lambda_2$ .

The last question that remained was how to find the  $\lambda = \lambda_1 = \lambda_2$ . In previous semesters, students had suggested plugging in  $y(t)$  or  $x(t) = Ce^{\lambda t}$  into the equation for the rate of change of  $x$  and solving for  $\lambda$ . This semester, students had recommended using substituting  $y = -x$  into the differential equations and getting closed form solutions for  $x(t)$  and  $y(t)$  as seen here:

$$\frac{dy}{dt} = -2x - 3y = -2(-y) - 3y = -y$$

$$y(t) = Ce^{-t}, \lambda = -1$$

A critical distinction of this curriculum from that which is traditionally taught is that eigenvectors develop before eigenvalues. Traditionally, one rewrites the linear system of differential equations using a matrix, finds the characteristic equation of the matrix and solves for the eigenvalues. The eigenvalues will give important information about whether solutions converge to or diverge from the equilibrium at the origin and whether there is any rotational motion in the phase plane as time evolves. However, eigenvalues are transparent in a particular context without fairly sophisticated mathematical understandings and techniques based on hundreds of years of mathematical development. Our goal was to provide students an opportunity to engage in guided reinvention of eigensolutions. The instructional design needed, therefore, to answer students questions about solutions rather than ones posed to them. Students investigated straight-line solutions to explain discrepancies from their predicted behavior of the motion of a dampened spring-mass system. This lead to questions that students could continue to address: What is the motion of the mass? How can we find what the limiting behavior is? Are there analytic solutions to these behaviors? This process mirrors student activity in the discovery of existence of straight-line projections. Straight-line solutions emerge first in this sequence and have meaning for the students related to the situation. Students originally discussed these straight-line solutions in reference to the motion of the mass. As the students developed understandings of these solutions, they were lead to using less context-specific ideas from which concepts and computation of eigenvalues emerged.

Another distinction is the opportunity for students to conjecture and test their conjectures formally. This appears many times in the instructional sequence. Stu-

dents conjectured what types of motion were possible for the spring-mass system. After their conjectures proved to be missing some cases, students then conjectured about the nature of these unpredicted limiting cases, such as whether they were lines and which lines they were. After making conjectures based on emerging intuition, students developed techniques to analytically prove their conjectures about finding the eigenvectors. Similarly, students made conjecture followed by more formal analysis for eigenvalues as well. This sequence gave students an opportunity to engage in the mathematical activity of reinventing the concepts and calculations behind eigenvalues and eigenvectors. Instead of supplying students with an algorithm and conducting analysis from there, students were able to come up with their own personal knowledge surrounding this topic and develop answers to questions posed by the instructor as well as their classmates.

Students practiced this technique with other linear systems of differential equations, and in the teaching experiment without videotaping, they were introduced to the technique of finding eigenvalues first and then getting eigenvectors. By the end of the semester, a majority of the students were finding the eigenvalues first as a means of finding analytic forms of solutions to linear systems. In both classrooms, most students demonstrated computational proficiency finding the eigensolutions for a generic linear system of differential equations in homework and on the final examination.

### **Conclusion**

RME has been used to develop a number of curricula at the elementary school level. It is only recently that these ideas have been used to develop undergraduate mathematics courses aimed at science, mathematics, and engineering majors. The principle of guided reinvention could be viewed with skepticism if applied to these courses, as the concepts and computations are more complicated than at the elementary level. Finding eigensolutions to linear systems of differential equations is considered one of the most difficult tasks for students in an introductory course to differential equations, both conceptually and computationally. Our research provides some evidence that students can develop both conceptual understanding and computational proficiency from this instructional sequence.

# **PROGRESSIVE MATHEMATIZATION IN ELEMENTARY GROUP THEORY: STUDENTS DEVELOP FORMAL NOTIONS OF GROUP ISOMORPHISM**

Sean Larsen  
Arizona State University  
larsen@math.asu.edu

The purpose of this paper is to report on a college-level teaching experiment in elementary group theory. The experimental “classroom” consisted of two students and the teacher/researcher. The teaching experiment was guided by the instructional design theory of Realistic Mathematics Education. Activities were designed to promote the guided reinvention of the concept of group isomorphism. The goal was to have the formal definition emerge from the mathematical activity of the students. The students were able to invent and apply procedures for determining whether two groups were isomorphic using group tables. They also demonstrated some progress in constructing a formal definition of isomorphism.

## **Introduction and Theoretical Perspective**

Leron, Hazzan and Zazkis (1995) described isomorphism as a “complex and compound concept, composed of and connected to many other concepts” (p. 153). Leron et al. advocated introducing isomorphism in the form of a naïve conception in which two groups are seen as isomorphic if “they are the same except for notation” (p. 154).

DeVilliers (1998) suggested that students should be actively engaged in the defining of mathematical concepts. My goal was to engage students in the defining of isomorphism. Consistent with the philosophy of RME, the aim was to have the formal definition emerge from the mathematical activity of the students. The instructional plan consisted of three phases. Note that although I wanted the students to *understand* the concept of isomorphism, the thrust of the project was to have the student reinvent the concept. (The theory is that students are more likely to understand and successfully use concepts that they have (re)invented themselves.)

Step 1: Encourage the students to develop a naïve conception of isomorphism (Leron et al., 1995).

Step 2: Encourage the students to invent procedures for determining whether two groups were isomorphic based on this naïve view.

Step 3: Encourage the students to generalize, abstract, and formalize these procedures in order to formulate a definition of isomorphism.

The instructional design and subsequent data analysis was guided by the instructional design theory of Realistic Mathematics Education (RME). RME is based on the notion that “mathematics can and should be learned on one’s own authority and

through one's own mental activities" (Gravemeijer, 1999). This idea is embodied in the first instructional design heuristic of RME, the *reinvention principle*. This principle does not suggest that students should reinvent everything for themselves. The more accurate term "guided reinvention" is often used to express the desired learning process. The goal is for students to feel ownership of, and responsibility for, the mathematics. Mathematizing (organizing from a mathematical perspective) is seen as the way to accomplish this reinvention (Gravemeijer, 1999). This includes horizontal mathematization in which one mathematizes a context-specific situation and vertical mathematization in which one's own mathematical activity is mathematized (Gravemeijer & Doorman, 1999).

One of the instructional design heuristics of RME is the notion of an *emergent model*. These models are called "emergent" because they emerge from the students' mathematical activity and because they support the emergence of more formal mathematical knowledge. Initially an emergent model surfaces as a 'model of' the students' mathematical activity. Subsequently an emergent model is used as a 'model for' supporting more formal reasoning. In the teaching experiments described here, the group table is seen to have initially emerged as a model of students' activity with geometric figures and then evolved into a model for supporting more formal reasoning including the construction of the concept of isomorphism.

### Methodology

The research design consisted of a sequence of three teaching experiments (Cobb, 2000; Steffe, 1991), each involving the researcher/teacher and two students. The retrospective analyses of each teaching experiment informed the instructional design of subsequent teaching experiments. Each of the participants had completed their first proof-writing course during the previous semester. Table 1 briefly describes the participants, including their academic major and the grade they received in the proof-writing course.

The teaching experiments consisted of seven or eight sessions each lasting 90 to 120 minutes. The sessions were videotaped and the students' written work was collected. The focus of this paper is on the later sessions of the teaching experiments in

**Table 1**

|                        | Participants | Major              | Grade |
|------------------------|--------------|--------------------|-------|
| Teaching Experiment #1 | Sandra       | None               | C     |
|                        | Jessica      | Math & Math Ed.    | A     |
| Teaching Experiment #2 | Melissa      | Computational Math | A     |
|                        | Leah         | Math               | A     |
| Teaching Experiment #3 | Debbie       | Math Education     | C     |
|                        | Nicole       | Math Education     | C     |

which the students constructed notions of the concept of isomorphism. To set the stage for this discussion, I briefly describe the first phase of the teaching experiments during which the group concept was developed. It was in these sessions that the group table emerged as a model of the students' activity with geometric figures and other physical objects.

The first few sessions of each teaching experiment were dedicated to the development of the group concept. The first activity required the students to identify the symmetries of an equilateral triangle and determine the result of performing any two of these transformations consecutively. The students physically manipulated the triangle and recorded their results in the form of a list. Eventually the students reorganized this information into a table. Additionally the students developed rules that could be (and were) used to complete the chart by performing calculations rather than manipulating the triangle. These rules included the group axioms and the dihedral group relations. Note that closure under the operation was not one of the rules the students developed at this point.

This process was repeated for the set of symmetries of a square in the first teaching experiment. For the second and third teaching experiments, the students also worked with the set of symmetries of a rectangle and the rotations of a square. Following these geometric activities, the students worked on two activities based on the game "It's a SNAP" described by Huetinck (1996). These activities involved a game board consisting of a rectangular array of pegs and some rubber bands. These activities provided physical examples of the symmetric group,  $S_3$ , and the Klein 4-group.

After completing the SNAP activities, the students identified the group axioms as the features that were common to all of the task settings. I introduced the term 'group' as a name for systems that satisfy the axioms. A discussion followed in which we developed a definition together. The most difficult aspect of this process was defining binary operation.

The students were then asked to verify that each element of a group must appear exactly once in each row and column of a group table. (This was an observation that all of the groups made early in their work with the geometric figures.) This led to the conjecture and proof of the cancellation law for groups.

### **Results From Teaching Experiment #1**

#### **Step 1: Developing A Naïve Conception Of Isomorphism**

My initial plan was to motivate the isomorphism concept by asking Sandra and Jessica to determine how many different groups there are with four elements. This question immediately sparked a debate.

Sandra: Why is it not infinite? Cause you have four elements, you know one of them has to be  $I$  because it has to have an identity. You have three other elements. Why can't it be any number in the real number system? I mean

why can't it be infinite. Because these could be twelve, two, and six or something or  $a$  and  $b$  and  $z$ . How many groups have four elements? I mean isn't it infinite number of groups?

Jessica: Well you can look at something with four elements like you said you take one is  $I$ . So you know this is going to be your chart. So basically how many ways can you fill this in so it would work and it would satisfy all the requirements of a group? How many different ways can you fill in these nine boxes so that it would have all the different ways to be a group?

Sandra: But that would just be with  $a$ ,  $b$ , and  $c$  as the elements.

Jessica: There's four different elements, those are just random elements.

Sandra: ...It's a different question. Do you see? This is how many groups have four elements. Well there's an infinite number of groups that can have an infinite number of four elements. Because you can take any element from anywhere. But this question is how many different configurations of a table can you get with four specific elements.

Jessica: I'm saying you have group with four, these four elements. Right? This is one group with these four elements. Now how many other groups can I make with these specific elements?

Sandra: Yeah. See it's a different question. I just don't like the way the question is phrased.

Eventually Sandra agreed that if the names of the elements of a group were changed, "a mathematician wouldn't think that it was any different."

### **Step 2: Inventing A Procedure For Determining Whether Two Groups Were Isomorphic**

Sandra and Jessica then constructed four different tables that satisfied the identity and inverse group axioms. To save time and tedious calculations, I assured them that the associative property also held for these tables. Then the question became whether some or all of the tables were really the same. The students identified the inverses for all of the elements in each group. It was agreed that the group in which each element was its own inverse was most likely different from the other three groups. At one point Jessica felt confident that two of the tables represented the same group.

Jessica: They are the same.

Teacher: Why? In what sense are they the same?

Jessica: Because if you just put  $c b a$  in here,  $c b a$ .

Teacher: So if I put  $c b a$  in here would you think it would be the same as...

Jessica: But you have to change these (motions to the interior of the table) accordingly as well.

It appeared that Jessica had a workable notion of what it means to change the names of the elements of a group. She appeared to be aware that one must change the interior of the table as well as the elements themselves. However, the students had difficulty developing a procedure for verifying that two of the remaining three groups were actually the same. In fact as they began to develop their procedure, their intuitive conception of isomorphism became unstable.

Jessica: I have a question. If we're changing things, we don't change the inverses. Right? Do we change the inverses? Or do we just have to...?

Teacher: Why do you ask?

Jessica: Does that mean we are just going to change these, or do you want us to change the inverses? Are there any restrictions, basically? Like you can't change inverses?

A moment later Sandra also indicated that she was unsure what it really meant to "change the names".

Sandra: I am still confused when you say change the names? Do you mean the set your starting out with to make the table or do you mean what's actually inside the table? And does it matter?

Later Sandra suggested that one should not change the names of the elements at all, but merely change the interior of one of the tables to match the interior of the other. She claimed that "there's nothing in the rules of the question that says you can't do that." I attempted to redirect Sandra back to the notion of naïve isomorphism by drawing two two-element group tables on the board, one with the set  $\{I, a\}$  and the other with the set  $\{I, b\}$ . She agreed that these two groups were the same and that this could be demonstrated if you "change the  $b$ 's to  $a$ 's". However, she protested that this was not the same situation as in the original problem because two different sets were being used while in the problem setting the same set was being used for each group.

After a lengthy discussion, the students' naïve conception of isomorphism appeared to stabilize. The students agreed that if the names of the elements were changed, the interior of the table must be changed as well. Eventually, the students were able to verify that the two groups were indeed isomorphic and wrote a description of their procedure (See Figure 1).

Sandra and Jessica were also able to use this procedure to determine that the two groups they had constructed with six elements (the symmetries of a triangle and one of the SNAP groups) were also isomorphic.

### **Step 3: Formulating a Definition of Isomorphism**

Sandra and Jessica made limited progress in formulating a definition of isomorphism. After their first renaming of the symmetries of a triangle did not result in the

1. Rename
 
$$\begin{aligned} a &:= b \\ b &:= c \\ c &:= a \end{aligned}$$
2. Fill out chart  
switching  $a, b, c$   
with new values.
3. Organize chart  
by switching columns and rows.

Figure 1.

table they had generated for the six element SNAP group, I challenged them to figure out why this renaming did not work. (The tables that the students generated for these groups are presented in Figure 2.)

Sandra: Shouldn't flip be able to be matched up with this one and this one and 6 because it's kind of the same relationship?

Teacher: Yes, that's what Jessica said. But it might matter which one you choose.

Jessica: It has to do with its combination with other things too.

The students were unable to be more specific, so I asked a more specific question.

Teacher: So you gave  $f$  a name and you gave  $r$  a name. You gave  $f$  2 and  $r$  4 right. Isn't  $f$  times  $r$  already determined in this table.

Sandra: That's the problem, the combinations. So you gave 2 a name of *flip* and you gave  $r$  a name of 4 but then  $fr$  is a name of 3 which is a problem.

Teacher: What do you think it should be?

| Triangle Group |           |           |           |           |           |           | Snap Group |   |   |   |   |   |   |
|----------------|-----------|-----------|-----------|-----------|-----------|-----------|------------|---|---|---|---|---|---|
|                | I         | R         | $R^{-1}$  | F         | FR        | $FR^{-1}$ | S          | 1 | 2 | 3 | 4 | 5 | 6 |
| I              | I         | R         | $R^{-1}$  | F         | FR        | $FR^{-1}$ | 1          | 1 | 2 | 3 | 4 | 5 | 6 |
| R              | R         | $R^{-1}$  | I         | $FR^{-1}$ | F         | FR        | 2          | 2 | 1 | 5 | 6 | 3 | 4 |
| $R^{-1}$       | $R^{-1}$  | I         | R         | FR        | $FR^{-1}$ | F         | 3          | 3 | 4 | 1 | 2 | 6 | 5 |
| F              | F         | FR        | $FR^{-1}$ | I         | R         | $R^{-1}$  | 4          | 4 | 3 | 6 | 5 | 1 | 2 |
| FR             | FR        | $FR^{-1}$ | F         | $R^{-1}$  | I         | R         | 5          | 5 | 6 | 2 | 1 | 4 | 3 |
| $FR^{-1}$      | $FR^{-1}$ | F         | FR        | R         | $R^{-1}$  | I         | 6          | 6 | 5 | 4 | 3 | 2 | 1 |

Figure 2.

Sandra: It should be...

Jessica: 6

Sandra: 6. Yeah.

In the hopes of encouraging the students to explicitly use a function to rename the elements of a group, I asked them whether the additive group of integers was isomorphic to the additive group of integer multiples of five. Jessica was able to make some progress in writing a definition. In the excerpt below, Jessica is explaining what she wrote to Sandra.

Jessica: You could multiply by five. Cause if you take everybody in here and you want to get something in  $5Z$  you just have to multiply by 5.

Sandra: That's right.

Jessica: And I was thinking it has to work the other way. So I said that they are isomorphic if there is a function from  $A$  to  $B$ ...it has to be bijective.

At this point I reminded the students that their first (unsuccessful) attempt to rename the elements of the triangle group was also a bijective mapping. Jessica responded by saying that it had to be a bijective function that "fits". The students then realized that the definition needed "something else". This missing property proved to be elusive; they had no trouble verifying in practice, however they were unable to articulate *what* they were verifying.

The discussion in which the definition was finally formulated was almost entirely teacher driven with the students' contributions limited to murmurs of assent. While the students were able to accept that a bijective function could be used to rename the elements of a group, they appeared to lack facility with function notation. This appeared to hamper their ability to participate in the final formulation of the definition.

Teacher: Jessica's already got us halfway done. She thinks that it would be a good idea if instead of using the word rename we have a bijective function. Does that make sense that a bijective function is the same as renaming?

Sandra: [Murmurs assent]

Teacher: OK, so we have a function. We want to say what it means. What did you call yours,  $A$  and  $B$ ?

Jessica: [Murmurs assent]

Teacher: Group  $A$  is isomorphic to  $B$  if and only if. You said there exists an  $f$  from  $A$  to  $B$  such that  $f$  is bijective (one to one and onto right) and we figured out that bijective isn't good enough.

[Additional discussion]

Teacher: Let's suppose I had  $a$  and  $b$  in the set  $A$ . What would I check to see if the renaming worked? First of all what are they renamed as? What is the new name for  $a$ ? How does the function rename it? Our function takes something in  $A$  to an element in  $B$ . Which element is that?

Jessica: This that transitive thing?

[Additional discussion in which  $a$  and  $b$  are changed to  $a_1$  and  $a_2$  to avoid confusion with the set  $B$ .]

Teacher: I take an element of  $A$ , it's going to be set to an element of  $B$ . Don't you know exactly what element that is or at least how to write it?

Jessica: [Quietly]  $f$  [pause, laugh] of  $a_1$ ?

Teacher: Yes!

### Discussion

The group table appeared to be somewhat useful as a model for supporting Jessica and Sandra's construction of the isomorphism concept. They were able to use group tables to articulate a naïve conception of isomorphism and to invent a procedure for determining whether two groups (given by tables) were isomorphic. However, the group table seemed to have limited value when it came to formulating a definition of isomorphism. In short, the students were more successful in using the group table for horizontal mathematizing than they were for vertical mathematizing.

Recall that I attempted to motivate the concept of isomorphism by asking the students how many different groups there were with four elements. This approach seemed to have introduced additional difficulties for the students. First, although the students were able to produce four group tables with four elements, these tables did not seem as meaningful to the students as the group tables they constructed from their own activity with physical objects. This may be part of the reason the students' naïve notion of isomorphism was unstable in this context. Second, the tables produced in this activity all used the same set of symbols for the elements. This seemed to be quite confusing for the students. As a result, this activity was delayed until near the end of

the second and third teaching experiments. Instead I motivated the concept of group isomorphism by presenting them with a new group table and asked them whether it could actually be one of the groups they had constructed. This appears to have been a more effective approach. Preliminary analyses of those teaching experiments suggest that the students' naïve conception was much more stable and that their invented procedures were more meaningful to them from the beginning. Interestingly, the problem of the sameness of symbols did reappear (in milder forms) in second and third teaching experiments when the students finally were asked to determine the number of groups of order four.

The three groups of students produced more than three different procedures for determining whether two groups are isomorphic from group tables. This variety that emerged suggests a strategy for facilitating the formulation of a definition of isomorphism. If different groups of students presented different procedures during class discussion, the subsequent comparison of procedures might serve to bring the operation preserving property (that is implicit in each of them) to the surface. The three groups of students also used different sets of symbols for the elements of their groups and their binary operations. In a whole class setting, these different representations of the same group could provide an early entrance into a discussion of isomorphism.

### Summary

The concept of group isomorphism is one of the fundamental ideas of abstract algebra. Based on the theory of Realistic Mathematics Education, I am working to develop an instructional approach that can make this concept personally meaningful to students. This paper reports on part of the initial stage of this project. A number of interesting observations emerged from the analysis of these first three teaching experiments. These findings indicate that such an approach can be successful while highlighting the complex nature of both the concept of isomorphism itself and the process of defining it through a process of progressive mathematization.

# **INQUIRY INTO THE INTERLOCUTION OF STUDENTS ENGAGED WITH MATHEMATICS: APPRECIATING LINKS BETWEEN RESEARCH AND PRACTICE<sup>1</sup>**

Arthur B. Powell  
Rutgers University  
abpowell@andromeda.rutgers.edu

Carolyn A. Maher  
Rutgers University  
cmaher@rci.rutgers.edu

For either to be useful, links between research and practice are critical. Just as important are connections between the practice of students engaged in mathematical activity and research that seeks to understand that practice. This research report explores lessons that researchers and practitioners can learn from an inquiry into the interlocution of students working collaboratively in small groups when engaged in talking and listening to each other. We use the term interlocution to denote discursive practices of learners in conversational exchanges. Questions that motivate this research included the following: What discursive practices do interlocutors employ as they work collaboratively to understand and resolve mathematical tasks? How do these practices influence the growth of their mathematical ideas? In what ways do their discursive practices help them move from a contextualized, situated task to generalize the task or their solution? Do students' discursive practices assist them to connect and generalize ideas from a new problem to others on which they have worked?

## **Background and Setting**

This report focuses on the development of mathematical ideas by individual students as they work collaboratively in small groups. More particularly, we analyze how students through their discursive practice structure their own investigations. The data come from an ongoing, fourteen-year longitudinal research project of the Robert B. Davis Institute for Learning, directed by Maher (Maher, in press, and for references to relevant reports), that has been conducted in public elementary and secondary schools in a suburban, working-class, and immigrant town of New Jersey. Overall, our longitudinal study aims to contribute basic scientific understanding of cognitive behaviors as well as pedagogical conditions for which mathematics learning occurs as a process of sense making. The participants in the present study are four students—Brian, Jeff, Michael, and Romina—in their senior year of high school who, from their entry into first grade have participated in mathematical activities of our longitudinal study. Over the years, these students have engaged tasks from several strands of mathematics, including algebra, combinatorics, and probability, both in the context of classroom investigations as well as in after school settings. For the present research report, these four students participated in an after-school session of mathematical problem solving. Data came from a culminating task, "The Taxicab Problem," in the research strand on combinatorics. The task has an underlying mathematical structure and contains concepts that resonate with those of other problems on which the students have worked

during their involvement with the longitudinal study. The participants potentially revisit and deepen mathematical ideas they have already built as well build new ideas. After the students worked on the problem for about an hour and a half, we interviewed them concerning the nature of their work so that we might follow movements in their discourse toward further justification of their solution.

### **Theoretical Framework**

Our research questions emerge from our ongoing, longitudinal investigation into the development of mathematical ideas by individual students as they work collaboratively in small groups (Davis & Maher, 1990, 1997; Maher & Martino, 1996, 2000; Maher & Speiser, 1997). The theoretical underpinnings of this investigation come from principally three sources: research on the development of representations (Davis, 1984; Davis & Maher, 1990, 1997; Speiser & Walter, 2000), models of the growth of understanding (Pirie, 1988; Pirie & Kieren, 1989, 1994) and theories about the generation of meaning (Dörfler, 2000). This report builds on these theoretical notions and explores the applicability of an additional conceptual framework concerning a particular discursive practice with the aim of understanding how students structure their own investigations through such a practice.

Grounded in philosophical ideas of Levine (1989) concerning the social evolution of human's capacity for listening and a movement toward listening that is an antidote for "alienated meaning" (p. 8), Davis (1996) develops a theory of pedagogical listening, according to three different modes of listening, not necessarily mutually exclusive: evaluative, interpretive, and hermeneutic. Evaluative listening occurs when a teacher maintains a "detached, evaluative stance" (p. 52). In contrast, a teacher listening interpretively endeavors "to get at what learners are thinking...to open up spaces for re-presentation and revision of ideas—to *access* subjective sense rather than to merely *assess* what has been learned" (pp. 52-53, original emphasis). Finally, Davis posits hermeneutic listening as "more negotiatory, engaging, and messy, involving the hearer and the heard in a shared project...an imaginative participation in the formation and the transformation of experience through an ongoing interrogation of the taken-for-granted...the unfolding of possibilities *through collective action*" (p. 53, original emphasis).

Recently, drawing on the Pirie-Kieren theory for the growth of mathematical understanding (Pirie & Kieren, 1994) and Davis's (1996) interpretive and hermeneutic listening, Martin (2001) observes teacher interactions in an elementary classroom to analyze how mathematical understanding grows at the individual and whole-class levels. He elaborates and provides evidence for how the listening patterns of a teacher can occasion opportunities for students "to construct and modify their own images in response to her interventions" (p. 251).

Both Martin (2001) and Davis (1996) inquire into teacher listening and its consequent impact on the growth of student understanding. Our study broadens this scope

of inquiry as well as applies and extends Davis's category to analyze not just listening but rather discursive practices of learners in conversational exchanges. This we call interlocution. Our category has four properties and guides the inquiry into how learners' discursive exchanges structure their investigation as well as contribute to the mathematical ideas they build and their growth in mathematical understanding. Emerging from new data within our longitudinal study, we analyze them in light of four properties of interlocution, three of which are adapted from the three listening modes that Davis (1996) proposes, which we define as follows:

- *Evaluative*: an interlocutor maintains a non-participatory and evaluative stance, judging statements of his or her conversational partner as either right or wrong, good or bad, useful or not.
- *Informative*: an interlocutor requests factual data to satisfy a doubt, a question, or a curiosity without evidence of judgment.
- *Interpretive*: an interlocutor endeavors to tease out what his or her conversational partner is thinking, wanting to say, expressing, and meaning; "to open up spaces for re-presentation and revision of ideas—to *access* subjective sense rather than to merely *assess*" it (Davis, 1996, pp. 52-53, original emphasis).
- *Hermeneutic*: an interlocutor engages and negotiates with his or her conversational partner; the interlocutors are involved in a shared project; each interlocutor participates in the formation and the transformation of experience through an ongoing interrogation of the taken-for-granted and the prejudices that frame perception and actions; the interlocutors "engage in an unfolding of possibilities *through collective action*" (Davis, 1996, p. 53, original emphasis).

Interlocution as a conceptual category in our research enables us to track the participation, growth in understanding, and autonomy of learners in their construction of mathematical ideas. Over the course of our longitudinal study, we have observed how individual learning occurs as learners participate in meaningful activities with other learners (Maher & Martino, 2000). Characteristics of these activities include not just the conceptually rich and open-ended nature of the mathematical tasks but also the research setting as well as how and when researcher-teachers intervene or not while learners engage in doing mathematics (Maher, 1998a, 1998b; Maher, Davis, & Alston, 1992). Over the course of our work, the role of researcher-teachers has evolved, increasingly becoming less interventionist and, after presenting a problem task and answering clarifying questions, being physically absent from where participants work.

### Method

Our data sources consist of video images collected from the different perspective of three cameras, each of the research session video's is about two hours in length; tran-

script of the videotapes combined to produced a fuller, more accurate verbatim record of the research sessions; student inscriptions; and researcher field notes. Our analytic method employs a sequence of phases, informed by grounded theory (Charmaz & Mitchell, 2001; Creswell, 1998; Pirie, 1998), ethnography and microanalysis (Erickson, 1992; Goldman-Segall, 1998), and approaches for analyzing video data (Cobb & Whitenack, 1996; Pirie, 1996, 2001; Powell, Francisco, & Maher, 2001). Specifically, our method of data analysis involves the following nine non-linear, interacting phases: (1) attentively viewing the videotapes several times without intentionally imposing a specific analytic lens; (2) describing consecutive time intervals; (3) identifying critical events; (4) transcribing the video record; (5) inductive and deductive synchronous coding of transcript, videotape, and inscriptions; (6) writing analytical memoranda; (7) categorizing codes, identifying properties, and dimensionalizing properties within categories; (8) constructing a storyline; and (9) composing a narrative. (For an elaboration and examples of these phases, see Powell et al., 2001).

### Results

The following is the combinatorial investigation on which participants were invited to work collaboratively, "The Taxicab Problem":

A taxi driver is given a specific territory of a town, shown below. All trips originate at the taxi stand. One very slow night, the driver is dispatched only three times; each time, she picks up passengers at one of the intersections indicated on the map. To pass the time, she considers all the possible routes she could have taken to each pick-up point and wonders if she could have chosen a shorter route.

What is the shortest route from a taxi stand to each of three different destination points? How do you know it is the shortest? Is there more than one shortest route to each point? If not, why not? If so, how many? Justify your answer.

With this problem statement, we gave the participants a map, actually, a 6 x 6 rectangular grid on which the left, uppermost intersection point represents the taxi stand. The three passengers are identified at three different intersections as blue, red, and green dots, respectively, while their respective distances from the taxi stand are four units south and one unit east, three units south and four units east, and four units south and five units east. (To more fully appreciate the episodes that we present below, you may wish first to work on the problem.)

Clockwise from the left, seated on three sides of a trapezoidal-shaped table are the four participants, Michael, Romina, Jeff, and Brian. At the start of the session, Researcher 1 pulls up a chair, sits on the right side of the table between Jeff and Brian, thanks the four students for coming, distributes the Taxicab Problem, and asks them to read and see whether they understand the task. Afterward, the researcher stands up

and, backing away from the table, removes her chair. With his head bent downward, facing the problem statement, Jeff asks aloud whether one has to stay on the grid lines and whether they represent streets. The researcher responds, "Exactly." Romina, Brian, and Jeff discuss that 5 is the number of blocks it takes to reach the blue destination point and that different routes to blue are the same length as long as one does not go beyond it. Brian says that they should prove it.

Researcher 1 walks back over to the table and asks the students for their understanding of the problem. Jeff says that the task is to find the shortest route while "staying on the streets." The researcher adds that it is about finding whether there is more than one shortest route. Both Brian and Romina voice agreement. The researcher goes on to say that if there is more than one shortest route, they have to determine how many there are. Jeff inquires whether the researcher is asking how many different shortest routes? Researcher 1 says that not only do they have to find the number of shortest routes but also that they will "have to convince us" that they have found all of them. The researcher then walks away from the table.

Jeff asks for colored markers. Jeff, Romina, and Brian choose to each work on different destination points. Romina says that it is five blocks to the blue point. Brian suggests counting them and being sure. Jeff asks why the length of each route to blue is the same. Michael explains that to get the blue point one has to go "four down and right one" since one cannot move backward or diagonally. Romina asks how to devise an area for that. Jeff and Michael tell her that it's not area, it's perimeter with each segment of the grid considered as one unit.

The above descriptive account is of the first four minutes and forty-four seconds of the research session. It is worth noting that the researcher spends little time at the table with the students and responds only to student questions in a tailored yet sparse manner. Also, the students rather quickly organize themselves by requesting colored markers and assigning subtasks to each other. When Jeff inquires about why the length or routes to the blue destination point are the same, Michael explains. When Romina requests help in devising an area, Jeff and Michael respond and inform her that the applicable notion is perimeter not that of area. In general, they also carefully and respectfully listen and respond to each other's questions, statements, and ideas.

After almost fourteen minutes into the research session, there is an interesting and pivotal interchange among Romina, Brian, and Jeff:

Episode 1: Break Apart and Do Easier Ones    Time interval: 0:13:42 to 0:13:54

Romina: I think we're going to have to break it apart and draw as many as possible.

Brian: Yeah, //that's what I'm going to do.

Jeff: //And then have that lead us to something? What if we do- why don't we do easier ones? You know what I'm saying? What if the- the thing- Do you have another one of these papers?

In Episode 1, An agenda for action emerges from this interlocution among the three students. Brian and Jeff accept the task implied in Romina's statement and act on her heuristic. Moreover, Jeff refines her suggestion in his interrogative: "why don't we do easier ones?" Romina's statement and Jeff's interrogative establish a new agenda for the group's actions. Importantly, this action agenda represents a milestone in their mathematical investigation. From this point onward, the students no longer work on the combinatorial problem as given and, instead, pose and work on simpler situations to glean relevant information and extract insights from those situations so as to inform their understanding and resolution of the given problem.

Following the heuristic approach that the participants articulated in the pivotal episode presented above, the participants continue their investigation with a renewed sense of purpose. They chose to work on a more general problem than the one the researcher posed but felt that it was simpler and sensed that it would, in the words of Jeff, "lead us to something." This new approach developed out of a brief but focused negotiation between Romina and Jeff. Romina presents an idea and Jeff listens, and responding to her idea, participates in an unfolding of possibilities. What emerged from their interlocution was a plan for collective action and illustrates one of four interlocutory mode or property observed within the data. Their discursive exchange is hermeneutic in the sense that both Romina and Jeff participate in a negotiation, an unfolding of possibilities, each listening to the other and co-constructing an idea.

The data suggest that particular interlocutory modes influence differently the progress of the group. We will first describe aspects of the work that the participants had accomplished by the time they were midway through the session and then quote from a long episode to illustrate further the different interlocutory modes.

In Episode 1 above, Romina, Brian, and Jeff decided to count the number of shortest routes by starting with simpler cases for intersection points nearby the taxi stand. Afterward, Romina and Jeff negotiate a method for counting. Starting with an intersection point that is 2 blocks east and 2 blocks south of the taxi stand (forming a 2 by 2 sub-grid), they count the number of shortest routes of several nearby points and record their results in the taxicab grid. Then, working with their 2 by 2 sub-grid for which they found 6 shortest routes, they work on a 3 by 3, finding 15 shortest routes. They also work on 2 by 4, 2 by 3, and 4 by 3 sub-grids. In this way, they control for variables, a heuristic that they had developed and employed in several earlier tasks in the longitudinal study.

At the start of the Episode 2 quoted below, Michael is double-checking that the number of shortest routes for the 3 by 3 sub-grid is 20. There is a brief, evaluative exchange of information between Michael and Brian, where the latter wants to know whether the former has included in his count a route whose trace has the shape of a staircase.

Episode 2: The Staircase One

Time interval: 0:55:31 to 0:56:42

Brian: Did you figure out the five by five?

Michael: Five by five? I'm doing three by three right now.

Brian: Let's just agree. If we already know what it is then we have to figure out-

Michael: I just want to make sure that's twenty. So- [Michael counts routes, moving his pen on his grid.]

Michael: I'm missing two. That's probably right though.

Brian: Did you get the, uh, staircase one?

Michael: Which one? For the three by three?

Brian: Yeah. [Inaudible]. [Romina returns.]

In the above, Brian, after Michael says that he is determining the number of shortest routes for a 3 by 3 sub-grid, inquires whether Michael found the "staircase one." The exchange involves passing on information and not evaluating responses. Brian lets Michael know the route whose shape is a staircase should not be overlooked. In this episode, the interlocutory property that characterizes the exchange between Brian and Michael is informative and leads to no externally expressed awareness or construction of mathematical ideas.

The next episode illustrates another mode of interlocution and points to its contribution the development of mathematical ideas. Romina had gone to the bathroom and rejoins the group.

Episode 3: Now It's Working

Time interval: 0:56:42 to 0:57:04

Brian: Did Jeff tell you?

Romina: What?

Brian: That this one-

Romina: For which one?

Michael: //For-

Brian: //Four by two.

Romina: So you did get fifteen? So now it's working? [Meaning that the pattern of shortest routes corresponds to Pascal's triangle.] And then the two by four has to be fifteen too. Now if we do three by three and that's twenty, then we're done.

In Episode 3, Brian announces to Romina that Jeff and he have verified that 15, not 12, is the number of shortest routes in a 4 by 2 sub-grid. Romina notes that 15 must

also be the number of shortest routes for a 2 by 4 sub-grid. In so doing, she voices her implicit awareness of a symmetrical property for the numerical pattern of shortest routes that Jeff and she have developed. Moreover, she observes that the pattern resembles that of Pascal's triangle. Romina listens, evaluates the information ("So now it's working?"), and interprets its meaning ("And then the two by four has to be fifteen too."). This episode establishes that a discursive exchange may involve more than one interlocutory property. In the present case, the interlocutor's words reveal that she engages both evaluative and interpretive interlocation.

At the end Episode 3, Romina suggests that if they can show that the number of shortest routes in a 3 by 3 sub-grid is 20, they can feel assured that their numerical pattern is Pascal's triangle. Michael and Jeff will assert that they will have to explain why numerical pattern is Pascal's triangle, and Romina will suggest relating their result to another problem they have worked on. However, at this point in their investigation, she, Michael, and Brian work individually to produce inscriptions of the different shortest routes in a 3 by 3 sub-grid. After about three minutes, she announces to Jeff that she is stuck.

Episode 4: How Do You Know It's Nothing Else?

Time interval: 0:59:49 to 1:00:34

Romina: I'm already stuck. [Brian draws a 3 by 3 rectangle on his paper. Romina draws in shortest routes for the "imaginary" 3 by 3 on her grid. Romina's pen stops when drawing a route.]

Jeff: You shouldn't be. Where you going?

Romina: Three by three. [She shows the paper to Jeff.]

[...]

Michael: Yeah I got twenty for that one.

Jeff: For a three by three?

Michael: Yeah.

Jeff: Alright well then- I mean can't we explain why we think- well- alright. [Jeff waves his hand.]

Michael: //They're going to ask us-

Jeff: //Alright then the next question is why- //why-

Romina: //Now-

Michael: //How do you know-

Romina: //Just relate this back to the //blocks. [Jeff points to the grid on the transparency with his marker.]

- Jeff: //But wait- Why is this- why does the Pascal's Triangle work for this is the question.
- Romina: //Exactly. Relate it to the blocks. [The word "blocks" here refers to the Towers Problem.<sup>2</sup>]
- Michael: //If it is how do you know it's twenty? How do you know it's nothing else?  
[...]
- Jeff: If we can explain why- why this is the Pascal's Triangle up to here [He points to the transparency grid.], we don't need to explain how we're positive this is twenty. //You know what I'm saying? [Jeff waves his hand again.]

A few minutes before the start of Episode 4, Romina voices concern about the group's datum for the 3 by 3 sub-grid. Brian offers to recount the routes for that one, and too creates inscriptions of the routes in a 3 by 3 sub-grid. Meanwhile, Michael has been counting the shortest routes for the 3 by 3 sub-grid and, in Episode 4, announces that he found 20. Suspecting that this confirms that their numerical pattern follows Pascal's triangle, Jeff states, "Why does Pascal's triangle work for this is the question." Michael echoes this question as well as states that the researchers are "going to ask us" this. Romina suggests relating their result to "the blocks," which is actually refers to "The Towers Problem," a class of related problems some of which are indeed isomorphic to the "Taxicab Problem."<sup>1</sup> Similar to Episode 3, in this one, the participants' conversational exchange has both an interpretive and hermeneutic interlocutory structure.

### Discussion

The four episodes presented above point to key mathematical ideas that the four students generate as well as heuristic and content connections that they make to other problems on which they have worked. Episode 4 illustrates that the students seek to understand and explain reasons why Pascal's triangle underlies the mathematical structure of the Taxicab Problem. Moreover, in the episode, Romina suggests that they relate (find an isomorphism between) this problem to the Towers Problem, a problem they have already met and resolved. As well, at the end of Episode 4, Jeff points to the numerical pattern on his and Romina's grid for the shortest routes for sub-grids smaller than a 3 by 3. Implicitly reasoning by induction, he then asserts that if they "can explain...why Pascal's Triangle works up to here [a diagonal of numbers above the entry 20 that represents a 3 by 3 sub-grid], we don't need to explain how we're positive this is twenty."

This and the other three episodes contribute and further our understanding of how learners develop mathematical ideas through their thoughtful engagement with task situations that they mathematize and of problem solving. Under the pedagogical con-

ditions of our research, the data suggest that learners collaborate to create agendas for action, that is, structure their method of investigation; co-construct an understanding of the task as its underlining structure; and build mathematical ideas synchronously as individuals and as collective members of a community of practice. Their co-constructions of heuristics and mathematical ideas emerge from informative, interpretive, and hermeneutic interlocation. A further outcome of the dominance of these interlocutory modes or properties is that over time learners build an *esprit de corps*.

Importantly, through specifically interpretive and hermeneutic interlocation learners do structure, monitor, and conduct their problem-solving investigation. In these interlocutory modes, the four participants of our study suggested subtasks for each other and ways of working, identified their need to verify expected outcomes and actual results, as well as prompted their need to explain and justify the underlining mathematical structures that emerged. As seen in Episodes 1 and 4, hermeneutic interlocation is a discursive practice in which learners structure their investigation of a mathematical task. As seen in Episodes 1, 3, and 4, learners engaged in interpretive and hermeneutic interlocation construct heuristics as well as mathematical ideas. Typically, evaluative and informative interlocation lead to no externally expressed awareness or construction of mathematical ideas. Tracking the properties of learners' interlocation yields insights into their mathematical ideas, growth in understanding, and autonomy as learners.

Though we have presented an analysis of episodes of a single problem-solving session, our observations of participants' mathematical engagement are informed by previous analyses in our longitudinal study (Kiczek, 2000; Kiczek, Maher, & Speiser, 2001; Maher & Martino, 2000; Martino, 1992; Muter, 1999). For instance, the evolved cultural norms of our research setting, most particularly the questioning patterns and expectations of researchers for explanations and justifications have been assimilated by research participants and infused into their ways of collaborating with each other. This is manifest in Episode 4 when Michael comments "they're going to ask us," and Jeff says "why does Pascal's Triangle work for this is the question."

Conversational interactions among learners can advance their subsequent individual and collective actions. Our data suggests that, among our four interlocutory properties, (1) interpretive and hermeneutic interlocation have the potential for advancing the mathematical understanding of individual learners working in a small group, (2) the personal or individual understanding of a learner is intermeshed with the understanding of his or her interlocutors, and (3) the mathematical ideas and understanding of an individual and his or her group emerge in a parallel fashion.

### Conclusion

The results of this study show that learners can autonomously structure, monitor, and conduct their investigation of a mathematical task. They can sustain their engage-

ment with a task for long periods of time and do so essentially without researcher-teacher intervention. We examined closely student interlocation and traced the development of their heuristic and mathematical ideas and growth of mathematical understanding. We have demonstrated how the discursive practices of learners influence how they structure their investigations, the mathematical ideas they develop, and how their understanding grows.

## DUELING DEFINITIONS: THE ROLE OF DEFINITION IN ANDREW'S UNDERSTANDING OF CONGRUENCE OF INTEGERS

Jennifer Christian Smith  
University of Texas – Austin  
JenncsmE93@aol.com

Developing an understanding of how to use definitions in mathematics has been regarded as a major hurdle for students at many levels. While studying modular arithmetic in a number theory course, undergraduates were observed using an incorrect pseudo-definition for the concept of congruence of integers, in addition to a standard definition given in class. In particular, Andrew seemed to understand the importance of definitions in mathematics, and recognized the inconsistency between the two primary definitions that he used for congruence. However, rather than reject one of the definitions, he chose to use both, inventing rules for when each was valid. Despite his success in the course, it appeared that he did not recognize that mathematical definitions should be consistent; that is, he did not appear to believe that all definitions for a concept should be logically equivalent.

Understanding the role of definition in mathematics has been characterized as one of the primary sources of difficulty for undergraduate mathematics students (Tall, 1992; Vinner, 1991; Dreyfus, 1991). Definitions are crucial in mathematics because of their ability to unify the related ideas of a concept across many fields of mathematics. Gray, Pinto, Pitta, and Tall (1999) argue that the transition from constructing a definition inductively from examples of a concept or mathematical object to constructing a mental object from a verbal definition alone is an extremely difficult one for students to make.

In an introductory number theory course at a large state university, students were introduced to the concept of congruence of integers as a tool for solving some classical problems in number theory. Congruence of two integers  $a$  and  $b$  modulo an integer  $n$  was defined in class in two ways:

1.  $a \equiv b \pmod{n}$  if and only if  $n \mid a - b$  [Standard definition]
2.  $a \equiv b \pmod{n}$  if and only if  $a$  and  $b$  have the *same* remainder upon division by  $n$  [Division-remainder definition]

The equivalence of these definitions was proved in class and the instructor made use of both definitions fairly equally. In the larger study from which the results presented in this paper are drawn, it was found that the students consistently interpreted statements of congruence incorrectly, using a pseudo-definition that they appeared to have collectively invented (see Smith, 2002). The pseudo-definition was generally stated as follows: " $a \equiv b \pmod{n}$  if and only if  $b$  is the remainder of  $a$  upon division by  $n$ ." Note that if one replaces the phrase "if and only if" with "if", this is indeed a true

statement. It represents a sufficient condition for two integers to be congruent modulo  $n$ , though not a necessary one.

The fact that this pseudo-definition is not equivalent to any other given definition for congruence did not appear to cause any conflict for most of the participants in the study. The case of Andrew, however, was different in that he acknowledged that the pseudo-definition was not equivalent to either of the definitions given in class. Despite the fact that he seemed to appreciate the significance of the role of definition in mathematics, he ignored the inconsistency between the two definitions.

### **Theoretical Perspective**

Vinner (1991) described the *concept image* as “something non-verbal associated in our mind with the concept name” (p. 68). In other words, forming a concept image for a particular concept is an inherent part of coming to understand that concept. Tall (1992) describes the notion of concept image more succinctly as “the total cognitive structure that is associated with the concept, which includes all the mental pictures and associated properties and processes” (p. 496).

Definitions in mathematics, according to Vinner (1991), form the crux of the “conflict between the structure of mathematics as conceived by professional mathematicians, and the cognitive process of concept acquisition” (p. 65). Vinner draws a distinction between “everyday life contexts” and “technical contexts,” noting that in most everyday experiences, one does not need to consult definitions in order to understand a sentence occurring in conversation. Indeed, some terms commonly used in everyday life, such as “red,” have no real definition. Instead, we each have a concept image for “red,” some aspect of which is evoked when we encounter this word. In general people have no need to revisit the definition of an understood concept; in fact, definitions in everyday life are quite dispensable. Vinner offers a “scaffolding” metaphor for this role of definitions; the definition may serve as a useful framework in learning a concept, but once the “building” is finished, the “scaffolding” is removed. In technical contexts, however, definitions play a much larger role.

According to Tall and Vinner (1981, as cited in Tall, 1992), the *concept definition* is “a form of words used to specify [a] concept” (p. 496). However, there does not appear to be a consensus in the literature as to precisely what this means. Vinner (1991) separates the concept definition from the concept image and allows for the possibility that an individual’s concept definition may conflict with the external formal definition used by the mathematics community. That is, the concept definition is a specific wording used by an individual to define a concept and thus is unique to the individual. This definition may or may not agree with the formal mathematical definition agreed upon by the mathematical community or taught to the student, but it is the definition that corresponds with the individual’s concept image. Tall (1991), on the other hand, uses the terms “concept definition” and “formal definition” interchangeably. For the purposes of this paper, the term “definition” will refer to a formal definition that is

accepted within the mathematical community, while the term “pseudo-definition” will refer to an incomplete verbal description that is regarded by students as a definition.

The definition for a concept clearly plays an important role in the learning of mathematics, especially in the development of proof. Tall (1999) writes that at the undergraduate level, “the introduction of axioms and proofs leads to a new kind of cognitive concept – one which is defined by a concept definition and its properties deduced from the definition” (p. 117). Students must begin to integrate their informal and formal concept images with these definitions in order to make the shift to the deductive nature of undergraduate level mathematics.

### **Method**

In the larger study, an exploratory case study design was used to investigate the conceptions of the concept of congruence of six undergraduates enrolled in an introductory number theory course. The participants, primarily pre-service secondary mathematics teachers, were chosen based on high scores on a first exam, in conjunction with Dr. Thomas, the instructor of the course. The researcher’s role was that of a participant-observer and unofficial teaching assistant in the course.

The six students participated in three semi-structured phenomenological interviews over the course of the semester. The first interview took place one week prior to the exam covering congruence, a second interview took place approximately two weeks later, and a third approximately three weeks after the second. In addition, class sessions during the unit covering congruence and applications of modular arithmetic were videotaped and transcribed. The data from which the results described in this paper are drawn come from the first two interviews with Andrew.

The first part of the first interview focused on the students’ experiences with and perceptions of mathematics as a discipline and of themselves as mathematics students. In the second half of the interview, the students’ responses to mathematical tasks on a previously completed worksheet were discussed. The second interview focused primarily on the students’ solutions to problems on the exam covering congruence.

### **Results**

Andrew was a quiet, introspective 20-year-old who planned to teach high school mathematics after graduation. His perspective on mathematics was unique from that of his peers, but like many of them he did not consider himself to be particularly good at mathematics. However, Andrew was extremely successful in the course, consistently earning the highest scores on assignments and exams. He intensely studied the text and other number theory books in order to gain further insight into the material. He was generally regarded by Dr. Thomas and the other participants as the best student in the class.

When asked what he liked most about mathematics, Andrew spoke first of his appreciation for the power of mathematics to unify concepts and ideas in many unre-

lated fields. He was aware that a shift in emphasis had occurred in his undergraduate mathematics courses in which the use of sophisticated theory and precise definitions played a larger role than it had in earlier courses. Andrew stated that understanding a mathematical concept entailed “being able to apply definitions very flexibly [...] comprehending an idea in its most general and abstract form and being able to apply the idea in a variety of situations.” Andrew’s use of language in describing his solutions to mathematical problems and tasks also revealed this emphasis on the importance of definitions in mathematics.

When asked in the first interview to explain the meaning of congruence of two integers  $a$  and  $b$ , modulo  $n$ , Andrew offered the following three definitions:

- 1)  $n$  divides  $a - b$
- 2)  $a$  divided by  $n$  leaves a remainder of  $b$
- 3)  $a = b + nk$  for some integer  $k$

When presented with a specific statement of congruence he tended to rely on the first [standard] definition, his language frequently revealing the significance he placed on definitions: “I’m sort of just re-churning again what the definition is saying, finding a number that meets these conditions.” Note that the second item Andrew offered is the pseudo-definition, and the third is algebraically equivalent to the standard definition. Like most of the participants, Andrew never used the definition of congruence that Dr. Thomas used in class – that  $a$  and  $b$  have the *same* remainder upon division by  $n$ .

One of the items on the worksheet used in the first interview consisted of four congruences, each with a variable in either the  $a$  or  $b$  position. The students had been asked to determine the possible values for the variable. Andrew’s written responses to these items are shown below.

Item: Andrew’s written answer:

- (a)  $x \equiv 3 \pmod{7}$      $x = 3 + 7k$
- (b)  $17 \equiv x \pmod{4}$      $x = 1, 5, 9, \dots, 4j - 3$
- (c)  $x \equiv 23 \pmod{11}$      $x = 23 + 11m$
- (d)  $2 \equiv x \pmod{9}$      $x = -7, -16, -25, \dots, 2 - 9m$

He had appeared to solve items (a) and (c) differently from items (b) and (d), and when asked if there was a difference between these congruences, he indicated that the position of the variable in the congruence was a factor, saying, “you’re talking about remainders here [when the  $x$  is on the right side] and you’re talking about finding numbers here [when the  $x$  is on the left side].” He explained that if one uses the second definition he gave [the pseudo-definition], there are multiple answers when the  $x$  is on the left, since there are infinitely many numbers that have a given remainder when

divided by  $n$ . When the  $x$  is on the right, however, he stated that there is a *best* answer, whose form was given by the division theorem. This reasoning was quite common among the participants in the study. In fact, several of the participants had insisted that there was only one value for  $x$  in items (b) and (d), while there were infinitely many values for the  $x$  in items (a) and (c) (see Smith, 2002).

When asked why he had in fact given multiple answers for items (b) and (d) in light of this explanation, Andrew explained that if one applied the first [standard] definition, then many numbers could be substituted for the  $x$  in these congruences. The interviewer then asked Andrew to consider what would happen if the positions of the numbers in item (b) were switched, so that the congruence read  $x \equiv 17 \pmod{4}$ . Would this change the congruence? Would there still be a *best* value to choose for  $x$ ? Andrew seemed to believe that it depended on the choice of definition.

"I mean, clearly when you take a number and divide it by four, especially this number [17], you will get a remainder of one, and not five or nine. But the congruence still works because of this [standard] definition. [Having one best value] would make more sense in terms of this [pseudo-] definition because by the division theorem, you couldn't have a remainder that's bigger than your divisor."

He seemed to believe that both the standard definition and the pseudo-definition could be applied in the situation, even though these were clearly not equivalent, and produced different solutions. Andrew appeared to believe that there were two different definitions for the concept of congruence, and the fact that they were not equivalent was not problematic.

A few weeks later during the second interview, Andrew remained firm in his belief that there were two different definitions for congruence. One of the exam problems asked the students to "fill in the blank" in two congruences: (1)  $33^{25} \equiv \underline{\hspace{1cm}} \pmod{8}$ , and (2)  $19^{19} \equiv \underline{\hspace{1cm}} \pmod{7}$ . Dr. Thomas' intention was that the students would use a "cycling" strategy<sup>1</sup> on the first item and Fermat's "little" theorem<sup>2</sup> on the second, though most of the participants described their initial attempts to solve these items in terms of using their calculators to find the decimal representation of the large integer, dividing this by the modulus, and finding the remainder (see Smith, 2002).

For the second item, Andrew had used Fermat's "little" theorem to find an answer of 19. However, he lost 2 points on his exam for not reducing this result to 5. He claimed not to have been bothered by losing points for this, but he was clearly convinced that his answer of 19 was correct.

A: I mean, it was like, once I saw what I'd written down, I instantly recognized what the mistake was. I don't think it was necessarily a mistake. I mean, the congruence is true. I don't know.

J: Do you think that's... that's a really good question now. I mean, what you've written here is true, right? But you didn't write 5.

A: Right, it doesn't make sense though ... in the world of mod 7, you're only talking about numbers zero up through six. So [19] doesn't really make much sense. But... you could really argue the point though that this is a true congruence. So, I mean... but no, I understand.

J: So, it's sort of analogous to leaving a fraction as  $2/4$ ? I mean, is that sort of the level of wrongness?

A: Yeah, I mean, I guess... I don't want to say that it's wrong. It's just... I don't know. I guess in some sense it's sort of a matter of convention. It's a very minor thing and I'm not too bogged down by it. I mean, as far as I can think, I mean, it's still right, you know. The congruence is still true, just like  $2/4$  is still  $1/2$ .

At this point, Andrew clearly was struggling with the inconsistency between the two definitions for congruence<sup>3</sup>.

Another item on the exam asked the students to solve for  $x$  in the congruence  $5x \equiv 1 \pmod{11}$ . Whereas all of the students had given a single number as an answer for items (1) and (2) described above, a *set* of answers was given by all students for this item. Andrew's answer was  $x = -2 + 11k$ . When asked if  $1 + 8k$  would have been a better answer for item (1), he responded that, though it would not have been wrong, it was not really an appropriate answer.

A: Well it wouldn't make sense in mod 8... If you're talking about the world of mod 8, it wouldn't be true that you'd get a remainder greater than 8. But the congruence would still be true.

J: When you say the congruence is still true, what does that mean to you exactly?

A: It means that if you took the difference between [the two numbers], 8 would still divide it.

Again, Andrew's use of two definitions for congruence was causing conflict. According to the pseudo-definition, the integer on the right side of the congruence was *the* remainder, and by definition, the remainder had to be smaller in absolute value than the modulus. On the other hand, the standard definition only required that the difference between the two integers be divisible by the modulus. By the end of the second interview, Andrew seemed to have become more entrenched in his belief that one could use two different definitions for congruence, even though these were at times contradictory.

### Discussion

The students' use of the pseudo-definition for congruence was an interesting phenomenon. Careful study of the transcripts of class sessions revealed that the instructor never used such language when referring to congruences in class, and though he generally showed a preference for reducing the integers on the right side of a congruence,

he also frequently did the opposite—substituting larger integers for smaller ones when this action facilitated the solution of a problem. All of the participants struggled with the role of the position of the integers in their understanding of congruence, though only Andrew recognized the importance of definitions in mathematics. He was the only student of the six who continually referred to definitions when trying to prove or verify statements involving congruence. Whereas the others tended to rely on their concept images when working with congruences, Andrew's first response was typically to refer to the concept definition – or definitions, in this case

In Andrew's experience, circumstances frequently arose in which the pseudo-definition was not satisfied, though the standard definition was. He did not seem particularly disturbed by this fact, merely confused and mildly frustrated. Rather than reject the pseudo-definition, he tried to understand the complex set of rules under which each definition could be applied. The fact that there were two conflicting definitions for a single concept was dealt with not by comparing the definitions, recognizing that they ought to be equivalent, and then rejecting the inferior one. Instead, Andrew accepted both and believed that use of one definition or the other was dictated not by logic, but by convention. It is interesting to note that he carefully applied each definition in the context that he considered appropriate, making certain that the conditions of the definition were satisfied.

Andrew was by all measures a successful mathematics student, and was one of the few in his peer group who had learned how to use definitions and mathematical formalism. However, he did not recognize that there should be a *single* definition for a concept, and that any alternative definitions should be equivalent. How had Andrew missed this important fact, which clearly contradicts his belief that the power of mathematics lies in its ability to unify concepts across many fields?

Definitions of concepts in "real life" can be contradictory; language can be twisted and words defined in such ways that their meaning in or out of a particular context is completely changed. However, this is not the case in mathematics. Mathematical definitions *are* consistent. The distinction made by Vinner (1991) between the use of definitions in real life and technical contexts applies to the perceived role of definitions in these contexts as well. Perhaps this subtle issue causes difficulty for students when they are learning to prove in mathematics. This research demonstrates that, at least in Andrew's case, not understanding the role of definition in mathematics caused a good deal of conflict and confusion. In his struggle to make sense of the concept of congruence, Andrew seemed to have come to the conclusion that he had to determine the nature of a set of arbitrary rules that clouded the concept of congruence in order to understand it.

Andrew was the only participant of the six in the study who seemed to appreciate the role of definition in mathematics, though all of the participants displayed the tendency to use contradictory definitions. Further research could be conducted with

advanced undergraduates in order to determine the extent to which mathematics students struggle with the role of definition, and to understand how a student's conception of definition affects him or her when learning to prove.

### Notes

<sup>1</sup> Using a "cycling" strategy would entail raising the integer 33 to a sequence of powers and reducing the result modulo 8 in order to find an exponent  $k$  such that  $33^k \equiv 1 \pmod{8}$ . In this instance,  $k = 5$  works, and so one can substitute 1 for  $33^5$  to get  $33^{25} = (33^5)^5 \equiv 1^5 \equiv 1 \pmod{8}$ .

<sup>2</sup> Fermat's "little" theorem states that if  $a$  is an integer and  $p$  is a prime that does not divide  $a$ , then  $a^{p-1} \equiv 1 \pmod{p}$ . In item (2), since 7 is prime, note that  $19^6 \equiv 1 \pmod{7}$ , so  $19^{18} \equiv 1 \pmod{7}$ , and then  $19^{19} \equiv (1)19 \equiv 5 \pmod{7}$ .

<sup>3</sup> It should be noted here that Dr. Thomas' grading scheme may have reinforced this difficulty. Though he did not specifically instruct the students to reduce integers on the right side of a congruence, most of the students did indeed do so. When asked about this incident, Dr. Thomas noted that he had been grading the exams quickly and had not immediately recognized that 19 was a correct answer. He noted that if Andrew had asked him about it directly, he would have re-awarded the points immediately. Andrew, however, decided not to pursue the issue. Another participant also gave 19 as answer, and like Andrew, decided that she must have made a mistake and did not ask Dr. Thomas why 19 was "incorrect." For more discussion of the social construction of the students' notions about the position of integers in a congruence, see Smith, 2002.

## **UNDERSTANDING COMPLEXITY: LINKING PHENOMENA TO REPRESENTATIONS**

Despina A. Stylianou  
University of Massachusetts Dartmouth  
dstylianou@umassd.edu

James J. Kaput  
University of Massachusetts Dartmouth  
jkaput@umassd.edu

This paper reports on results of an exploratory study on undergraduate students' understanding of complex systems' ideas across varied representation systems. The study described two groups of students' explorations of a physical device which exhibits complex dynamic behavior. Students could manipulate the device and observe it both directly and through graphs. Through their interaction with the device, their use of familiar types of representations, as well as analogies to familiar events and devices, students gained entrance to the complex phenomena and the ideas that underlie complexity. As their familiarity with the device increased, students used it to understand new representations and to reconstitute elementary mathematical ideas. While in the first case students used a previously mastered representation system as a means to understand complexity, in the second case they developed a new representation system by experiencing it in relation to previously understood phenomena.

The ideas of complexity are increasingly becoming an integral part in the mathematical, physical, biological, and even social sciences. The conceptual basis of complex systems ideas reflects a change in perspective about our world that is important for students to develop, as it corresponds to the scientific environment that will exist when they graduate (Chen & Stroup, 1993; Kaput, Bar-Yam, Jacobson, Jakobsson, Lemke, & Wilensky, 2001). This perspective emphasizes both the limits of predictability as well as the possibility of understanding indirect consequences of actions taken through modeling the interdependence of our world (Hall, 1992; Prigogine, 1999; Tufillaro, Abbott & Reilly, 1992).

Despite the wide recognition of the broad applicability of complex systems' models in our world, these ideas have not yet found their position in our curricula. Except for the education of a few highly trained specialists, little of the conceptual power embodied in the rapidly developing tools and perspectives of complex, dynamical systems has reached the educational experience of our citizenry at any level. Recent research in student learning has shown that many of the core ideas of complex systems and nonlinear dynamics are challenging for most students (Casti, 1996; Feltovich, Spiro & Coulson, 1989; Jacobson, et al., 1998; Kaput et al. 2001; Resnick, 1996; Roberts, 1978; Wilensky, & Resnick, 1999). For example, many students, even at the college level, believe that chemical reactions stop at equilibrium (Kozma, Russel, Johnston, & Dershiimer, 1990). Further, many concepts related to complex systems may be counter-intuitive or conflict with commonly held beliefs (Casti, 1996). Students often

expect a linear relationship between the size of an action and its corresponding effect: a small action is expected to have a small effect, while a large action a large effect correspondingly. However, it is now well-understood that in complex and dynamical systems a small action may have interactions in the system that contribute to a significant and large-scale influence – the “butterfly effect”. Other researchers have proposed that people tend to favor reductive explanations that assume central control and deterministic single causality and that there is a deep-rooted resistance towards ideas describing various phenomena in terms of self-organization, and decentralized processes (Feltovich, et al., 1989; Wilensky & Resnick, 1999).

Further study is warranted to determine how students develop an understanding of these ideas, and what are appropriate learning experiences and instruction activities to support students’ learning. This study, whose purpose includes an investigation of the ways that students approach and come to understand complexity, aims to provide insight into this issue. Specifically, we examine

- (i) How can interaction with complex physical systems lead into the core ideas, representations and phenomena of system dynamics.
- (ii) How a physical complex system can act as a medium for reconstituting certain key traditional ideas, some of which are at the heart of classical calculus and basic kinematics.

### **Method of Inquiry**

We designed a study to begin to explore the above issues based on prior work and apparatus developed by Ricardo Nemirovsky. Our prototypical tool is the Bouncing Car device (Figure 1), a small car sliding on an inclined plane and colliding with a moving piston on the lower end of the plane. The piston is driven by a motor and it moves periodically. As the piston moves, it may interact with the “car” that can bounce against the piston and move up and down the inclined rack. Each time the car is bounced up the rack, its velocity after impact determines the distance (and time) the car will travel up the rack and return to the piston again, which determines how far the car will travel (bounce) the next time. This is the origin of the non-linearity of this model.

This device provides a manipulable and visually explicit version of a nonlinear dynamical physical system studied by Tufillaro et al. (1992), which involved a ball bouncing on a vibrating table. The amplitude and the frequency of the oscillating piston can be modified as it moves. Based on a motion sensor, a computer generates real-time graphs of various kinds for both the car and the piston. These graphs can display various data (velocity or position vs. time, velocity vs. position, etc.) which can be displayed separately or simultaneously on the same screen if desired.

The Bouncing Car is one of a family of physical devices developed such that they can exhibit a wide range of dynamic behaviors, their inner workings are visible and

Figure 1. The Bouncing Car.

open to examination and control, and their motion is symbolized with real-time graphs generated on a computer screen. These three features, coupled with the fact that these systems are physical, tangible, are critical to students' engagement with the science and mathematics of system dynamics (Corrêa, 1997; Noble, Nemirovsky, Wagoner, Solomon, & Cook, 1996).

We used the device to interview two groups of undergraduate students. The first group consisted of 5 students and the second consisted of 3 students. All students had a strong background in mathematics (each participant had completed on average five college-level mathematics courses). Each interview lasted approximately 3 hours. Students were asked to explore the device in order to understand its function. The interviewer kept a non-interfering stance and allowed students to pursue the questions they found interesting. Both sessions were videotaped and transcribed and were analyzed using a qualitative methodology. The method of analysis involved inductively deriving the descriptions and explanations of how the students interacted with the device and approached selected dynamical systems ideas with a focus on periodic vs. chaotic behavior, and sensitivity to system parameters, which in this case were the period and amplitude of the piston's motion and the slope of the inclined plane. Using related behaviors and comments within each topic, we wrote descriptions of the students' operations and actions. These descriptions formed the findings of the study.

### Results

Complexity can be found in almost any physical system – both in a technical and informal sense. In the technical sense, complex systems are sets of interconnected elements whose collective behavior arises in a non-obvious way (and often counter-intuitive and surprising way) from the properties of the individual elements and their interconnections. In the everyday, informal sense, complexity suggests that many

phenomena are happening simultaneously in a way that is difficult to comprehend. Clearly, students experience complexity in both senses in their everyday lives. However, students seldom, if ever, are exposed to a situation where they have to understand and represent complex phenomena in the technical sense. Throughout their schooling students are only asked to study instances within phenomena that are carefully chosen to *avoid* complex behavior. In some ways, this follows the epistemological pattern of Western Science of the past several centuries – avoid and idealize away phenomena that are not subject to simple, universal and often closed-form mathematically expressible laws (Casti, 1989). In our interviews students were faced with complexity in both senses. Thus, it was not surprising that both groups initially expressed a need to “regulate” the motion of the car. Students attempted to adjust the device and the car to achieve what they tried to describe as a “consistent”, “periodic”, “equilibrium”, “regular” and, “harmonic” motion. It was these attempts to regulate the motion of the car that formed the context of their explorations and their discussions of their explorations of complexity. Here, we describe the ways in which students first came to develop insights into certain core ideas of system dynamics (which, of course intends simplicity of description and modeling as well, but in a way that includes many of the phenomena that were, in principle, ignored by traditional science (Hall, 1992). Secondly, we describe how students’ understanding of other mathematical concepts interacted with the development of their understanding of these ideas.

### **Understanding the Core Ideas, Representations and Phenomena of System Dynamics**

Throughout the interviews students used a variety of ways to organize the complex behavior they witnessed. Over time students used different viewpoints in their attempt to decipher the complexity they faced: experimenting with the device itself, studying the graphical representations of the motion, and forming analogies to other experiences with physical devices and functions.

#### **Studying graphical representations**

During interviews students often used a visual approach in which they qualitatively analyzed the graphs that represented the motion of the bouncing car. Students questioned the local and global meanings of graphs, and attempted to form conjectures on the nature of the motion and possible functions that model the motion. When the students in the first group first saw the distance vs. time graph of the motion of the piston and the bouncing car (Figure 2), they attempted to qualitatively analyze the graph and gain insights into the motion of the bouncing car. As experienced users of distance vs. time graphs, they could see the graph as a description of an event. Don had predicted that the piston’s movement would be described by a sine function and was surprised to see the graph that the motion detector gave him:

Paul: “The blue graph [lower graph in Figure 2] is constant. It’s the piston going back and forth”

Don: "It doesn't go below zero! It's like a vertical shift..."

Paul: "No I don't think. It's different, it stops [...] Where is zero?"

Don: "It's here, at the end. It comes out and then back again. And there's these stops..."

The two students attempted to use the graph to understand the motion of the piston, which, initially, appeared to be periodic. They trusted their reading of the

Figure 2. The distance vs. time graph of the piston (lower graph) and the car (upper graph).

graph to interpret the motion of the piston. Similarly, they attempted to understand the motion of the car using the same graph:

Paul: "Those casps... where it's changing direction. It's when the car hits the piston. It goes "boom" and it bounces back."

Joyce: "It's changing sharply. That's obviously when it's hitting the bumper"

Joyce and Paul once again interpreted the motion of the car using the well-understood graphical representation. The second group followed a similar path and moved further to attempt to predict the distance the car travels based on its interaction with the piston – but as mediated by the graphs rather than the phenomena directly:

Andrew: "See, how far it [the car] goes depends on whether the piston is going inward or backward"

Mike: "Yes, see when it hits it when it's coming out, it goes farther"

Andrew: "This is the way I see it [moves toward the white board and starts drawing a graph]: When it [the car] hits it [the piston] when it's [the piston] decreasing it doesn't go very far."

Ilda: "Yeah, sometimes it just bounces back..."

Mike: "I want to change the speed and the amplitude of the piston. I want the car to hit always at the same time. We should time it. Then it [the car] will always go up the same distance"

The second group put aside the device and worked directly with the visual representation which appeared to be a powerful tool in their hands. While they responded to the graph as an object, they saw through the graph to what it represented and felt confident in forming predictions about the behavior of the device based on the relationships they could extract from the graph. Furthermore, contrary to common expectations, students in both groups did not reduce the complexity of the situation into isolated pieces with which they felt comfortable. Rather, students often *chose* to use the visual complexity of the graphs to aid them gain insights into the situation they were exploring.

#### **Forming analogies between the device and previous experiences**

In several occasions students drew analogies between the bouncing car device and other physical situations where collisions occur. The following excerpt from the first group's interactions illustrates the use of analogies as a tool to manage complexity:

Paul: "See, when it [the car] hits it [the piston] and it follows through, it goes farther away. Like a baseball bat [imitates the swing of a bat]. If you hit it at the end of the swing it doesn't go far, but when you hit it during the motion you follow through. The motion goes all the way through."

Don: "Yeah, like in golf..."

The game of baseball or golf is another familiar situation and students used it to understand the factors that determine the motion of the car relative to the piston. In other cases, students attempted to find similarities and differences between this device and objects that exhibit periodic motion. These findings resonate with earlier work of Clement and Brown (1988).

#### **Experimenting with the device itself and the interactions with the device**

During the second part of the two group interviews, students were presented with a second representation of the bouncing car motion, the velocity vs. distance graph (Figure 3). It has been observed that students have little familiarity with the velocity vs. distance representation of motion (Leinhardt, Zaslavsky & Stein, 1990). Students'

discomfort with this representation became immediately obvious in their behavior towards the graphical representation and the Bouncing Car device. In this case, students not only did not utilize the graph to gain information about the device, but they turned their attention to the device as a means to gain insight into the nature of the graph – a complete reversal. As one student in the first group commented

Joyce: “I’m not familiar with this graph; it’ll be harder to understand the car’s motion by looking at the graph... I’m trying to think of what is happening with the car to understand the graph”.

Similarly, Andrew in the second group asked his teammates to turn on the bouncing car device for him to observe the formation of the graph while the car was moving:

Andrew: “I want to see how those circles are formed. Turn the thing on again and slow it down. I want to see it drawing the graph”

The direct and observable connection between the graph of the motion of the car and the piston on the computer screen and the actual motion of the car and the piston on the Bouncing Car device allowed students to interpret the graph directly, in terms of their own actions and the behavior of the device. Andrew and his group attempted to interpret each element of the velocity vs. distance graph by watching it while it was

Figure 3. The velocity vs. distance graph of the piston (small ellipse on the left) and the car.

being formed. He watched the device carefully to see what the intersections of the two graphs meant and how the changes in the car's direction, velocity and distance were represented on the graph.

The ways with which students operated on the device differed qualitatively across students, which indicates differences in the underlying conceptualizations of the functions they are working with (a finding that resonates with earlier work by Monk, 1994). For example, a number of students worked in a playful, spontaneous mode with the hands-on device and watched the graph being formed, while, others carefully manipulated the various features to achieve certain outcomes and to test explicit conjectures – a qualitative but systematic exploration of the situation.

### **Interaction Among Ideas Underlying Complexity and Elementary Mathematical Ideas**

#### **Using elementary mathematical ideas to understand complexity**

As discussed above, students often used elementary mathematics to gain insights into the complex behaviors. In our case, it was the contrast of the graph of the periodic motion of the piston to the graph of the non-periodic motion of the car that helped students start understanding the variables that were possibly affecting the motion of the car. In addition, with experience of various kinds of quasi-periodic motion, students gradually came to develop insights into the concept of various types of periodic orbits in phase space representations (plots of velocity against position in this case).

#### **Using new representations of the complex system to reconstitute elementary mathematical ideas**

The study of the phase-space graph of the bouncing car motion involved the use and, subsequently the re-examination of elementary mathematical concepts such as the concept of a function. Students questioned the idea of a periodic function and the meaning of the intersection of graphs (ideas which become problematic in the context of velocity/position graphs) and attempted to interpret these concepts and representations in the context of these new representations of the bouncing car device. Their experience with the physical device exhibiting a complex behavior in a relatively novel notation system revealed in some cases weaknesses in their understanding of key mathematical concepts, or provided a new perspective and context to their previous knowledge.

### **Conclusions**

As with Noble et al. (1996), we feel that complexity, in the informal sense, is often what makes a topic interesting. Further, complexity allows multiple ways to enter an investigation, and, hence, multiple ways to connect with the topic, especially when the topic is complex systems in the technical sense, bringing in and connecting previous experiences in the new context. Students in this study explored the device, and sub-

sequently concepts of complex systems using multiple perspectives, and, even though their understanding of the specific ideas was rudimentary, it not only became richer as their explorations progressed, it provided a basis for revisiting core ideas from their traditional mathematical background. As students connected the motion of the device to previously learned mathematical concepts and to other physical phenomena, their previously established knowledge was destabilized and began to be reconstructed in new and richer ways as was argued by Noble, Nemirovsky, DiMattia, and Wright. (2002).

Our findings suggest that one of the critical sense-making elements was the link between the graphical representations and the actual device or phenomena that took place. Students resorted to their strong understanding of certain types of representations to interpret the new phenomena. Graphical attributes were interpreted as actions of the bouncing car. However, when the representation system was less familiar, students used their newly acquired knowledge of the device to give meaning to the representation.

Overall our results suggest that students, instead of avoiding complexity, embrace it and use it to build new understandings. Indeed, we see an enormous opportunity to approach an important topic, currently very underrepresented in students' educational experience, while simultaneously reconstituting traditional concepts. A major initiative is needed to determine how students can learn these ideas, as well as what are appropriate learning experiences and instruction activities that support students' learning. Of particular interest is determining how to integrate traditionally important topics as well as new topics in ways that are broadly implementable. We should use complex systems ideas and methods to unify and render more coherent students' educational experiences in the same ways that these ideas and methods are helping unify and organize knowledge across traditional boundaries.

# COLLEGE STUDENTS' CONCEPTUAL LINKS BETWEEN THE CONTINUITY AND THE DIFFERENTIABILITY OF A FUNCTION

Karina Viveros  
Instituto Politécnico Nacional  
kviveros@ipn.mx

Ana Isabel Sacristán  
Cinvestav-IPN  
asacrist@mail.cinvestav.mx

In this paper, we report results from a study that researched the way in which college students relate two important properties of a function: its continuity and its differentiability. In particular, we investigated students' interpretations of part of the Fundamental Theorem of Calculus (*"If a function  $f$  is differentiable in a closed interval, then  $f$  must be continuous in such interval"*), and the influence and use of different representational registers. Fifty-five Mexican college students answered 3 questionnaires designed to get insights into the use of the algebraic and graphic representational registers when determining whether a function is continuous and differentiable. Eleven of these students were also asked to answer similar questions to those on the questionnaires, but using the software DERIVE, in an attempt to compare their approaches with and without the use of technology. In both cases there was a predominant use of the algebraic representational register, with students tending to consider that continuity implies differentiability.

## Introduction and Theoretical Framework

The focus of our research was to investigate the way in which college students relate two important properties of a function: its continuity and its differentiability. When researching the literature, we were surprised by the lack of research dealing with the ways in which these two mathematical properties are conceptually linked by students. There is a wealth of research on students' conceptions of continuity and of the concept of derivative, and some evidence that many students are not clear about the relationship between those two properties of a function; however, there is scarce research on the ways they connect these two interlinked concepts. Thus, the purpose of our study was to get insights into the ways in which students use the continuity or non-continuity of a function in order to determine the differentiability of that function: specifically, on how they use or misuse the theorem *"If a function  $f$  is differentiable in a closed interval, then  $f$  must be continuous in such interval"*, that is part of the first form of the Fundamental Theorem of Calculus. We were particularly interested in analyzing the influence and use of the different representational registers during the determination process, since both the continuity and the differentiability of a function can be studied through algebraic or graphical approaches.

For example, the concept image of a continuous function, often involves the thought of a function whose graph can be sketched without lifting the pencil, a graph without "holes" or "jumps;" and that of a differentiable function could evoke the

image of a function with a “smooth” graph “without spikes.” These are the visual characteristics that can be considered in relation to the continuity or differentiability of a function. We wanted to see how much students use or depend on these visual characteristics, and how much they connect them with the results of algebraic analysis. In his work on representational registers, Duval (1993) points out that the power to move between different registers for a same object, seems to be a necessary condition for the mathematical objects not to be confused with their representations, and so that they can also be recognized in each of them. He points out that for the proper understanding of a concept it is necessary to coordinate the representations in (at least two) different registers of that concept. The absence of coordination between different registers does not hinder all understanding, but limits the understanding to the use of a single representational register, which in turn is not optimal for learning.

### **A Historical Analysis of the Notions of Continuity and Differentiability**

As a background for our research, we carried out a historical analysis of the notions of continuity and differentiability. We consider this historical aspect relevant since it has been observed (see Piaget & Garcia, 1989) that often students give similar arguments and exhibit similar cognitive processes to those that have appeared in the historical development of science.

To discuss in detail the historical analysis is beyond the scope of the paper, but we would like to point out some interesting events.

In relation to the concept of continuity, it is interesting to note some of the evolution of that concept. In the 18<sup>th</sup> Century, Euler and Lagrange considered that a function was continuous if it was defined by a single algebraic expression. In 1767, Euler defined discontinuous functions in the following way: *all the curves not determined by a defined equation from the usual class, that are sketched by a free-hand movement* (Youschkevitch, 1976). This indicates he considered as discontinuous those curves that are produced by what are today called functions defined by parts; also, those curves were not considered genuine functions (Monna, 1972). But what is also interesting in this, is the relationship between the graphical representation and the algebraic one: it was not enough for a curve to look continuous; it had to be defined by a single equation. It wasn't until the work of Bolzano, Cauchy and later Weierstrass that the notion of continuity evolved to its present meaning.

In terms of the relationship between continuity and differentiability, it is interesting to note that up to the 19th century it was considered that the continuity of a function was sufficient for a function to be differentiable almost everywhere—Ampère, among others, believed in 1806 that any continuous curve had to have tangents everywhere except maybe in some isolated points (Ribnikov, 1987). Even Cauchy, who later, along with Bolzano, contributed to construct the formal definitions of the concepts of continuity and of derivative also originally believed, like most mathematicians of that time, that a continuous function had to be differentiable (Kline, 1972). But in 1817, Bolzano

ended with this conception, when he presented a continuous function that was nowhere differentiable. After Bolzano, many mathematicians gave examples of non-differentiable continuous functions: e.g., Riemann, Cell  rier and Weierstrass (whose example, the Weierstrass' function, is the most well known, since Bolzano's example remained generally unknown for a long time). The historical significance of such discovery was the realization that continuity does not imply differentiability.

### **Literature Review and Background for our Research**

In the mathematics education literature, we have found that many works that have focused on the notions of continuity and/or of the derivative of a function show as common result that many students are not clear about the relationship between the continuity and the derivative of a function (e.g., Artigue, 1991, Lara, 1998): for instance, some students consider that the visual characteristics of the graph of the derivative of a function are determinant factors for the continuity of the function (Tall & Vinner, 1981). These were the kind of results that motivated our interest in studying the ways in which students link the two notions of continuity and differentiability.

Other results also point to a lack of integration of the different representational registers and a prevalence of the algebraic register. It has been found that many students are fixed in the use of the algebraic derivative algorithms (Orton, 1983); and that they avoid working with graphs, always looking for the algebraic expression (Artigue, 1991). In general, students are unable to sketch the graph of the derivative a function from the graph of a function, or vice versa, and show confusions between the meaning of continuity and of differentiability (Artigue, 1991).

Research related to the notion of continuity has found that, in general, students don't take into account the domain of definition; they tend to consider that a function is continuous if its graph is connected. Thus, they believe that functions with the following characteristics (regardless of the domain of definition) are not continuous: those whose graphs are not in a single piece, those not defined in the origin, those that diverge to infinity at the origin (Tall & Vinner, 1981). Sometimes students consider that a function is continuous if it is defined for all the real numbers. On the other hand, often students think that a function that is defined by parts cannot be continuous (Tall & Vinner, 1981), which is one of the conceptions also found in history (as explained above, both Euler and Lagrange considered that a continuous function had to be defined by a single algebraic expression).

### **Design and Methodology of Our Study**

As stated above, the purpose of our study was to get insights into the ways in which students use the continuity or non-continuity of a function in order to determine the differentiability of that function; we were also interested in analyzing the influence and use of the different representational registers during the determination process. There were two phases to the research: the main one using paper and pencil questionnaires, and a small limited second phase implementing computer-based activities.

The subjects were fifty-five Mexican college students studying towards a degree in computer engineering. These students had all passed a first Calculus course where they had studied all the notions that we deal with in our research. That course was taught in a traditional way without the use of technology such as computers or graphing calculators, except in rare occasions for producing sketches of graphs. The research was carried out at the beginning of their second semester of studies: these students were enrolled in two groups, randomly selected, of a second Calculus course.

### The Questionnaires

In the first part of the research, we used three written questionnaires: the first two were used to give us background information that could be correlated for analysis purposes with the answers of the third questionnaire, which was our main interest and which is the one we describe below. These first two questionnaires were designed to get insights into students' conceptions on, respectively, the continuity and the differentiability of functions; the third questionnaire focused on how students associated the two notions. All three questionnaires presented functions in different ways, in search of insights into students' conceptions with reference to the two different representational registers (the algebraic and graphical) and the ways they coordinated the information in the two registers.

The third questionnaire had 7 items, which included: Four questions where students were asked to determine the continuity and differentiability of several functions given in both algebraic and graphical ways:  $f(x) = -x^2 + 1$ ; and  $f(x) = |x|$ , both defined in the real numbers; a function defined in parts, with points of discontinuity in its domain; and another function also defined in parts but continuous in its domain of definition. The fifth question (see Fig. 1) only showed the graph of a function and students were asked to determine the points of discontinuity and the points without derivative.

In the last two questions the functions were given only through their algebraic representation: one (in question 6) was a continuous function but defined in parts,

Figure 1

which had some non-differentiable points  $f(x) = \begin{cases} 0 & \text{if } x \leq -2 \\ x+2 & \text{if } -2 < x < -1 \\ 1 & \text{if } -1 \leq x \leq 1 \\ -x+2 & \text{if } 1 < x < 2 \\ 0 & \text{if } x \geq 2 \end{cases}$ ; and the other (in question 7) was  $f(x) = \frac{1}{x+1}$  defined in  $R - \{-1\}$ , whose graph (not given to students)

is visually disconnected.

Many of the questions used, were taken or inspired from previous research (e.g. Tall & Vinner, 1981; Orton, 1983; Artigue, 1991; Eisenberg & Dreyfus, 1991; Dolores, 1998), which allowed us to compare, as far as possible, our results with theirs.

As an analysis methodology, we classified the answers to the three questionnaires in several categories, some of them referring to the use that students made of the different representational registers. For example, we classified answers where students referred to formal definitions (either correctly or incorrectly) in the category named "formal idea"; if students gave visual arguments, we classified their answers in the "visual idea" category. We also had a mixed category called "formal-visual" for answers that used both types of arguments.

### The Computer-based Activities

In the second phase, we attempted to observe if there were differences in the use of the representational registers when determining the continuity and differentiability of a function, using only paper and pencil or using a computational tool: the software DERIVE. The use of technology and of multi-representational systems has sometimes shown (e.g., Jones, 1993) to produce a better learning by helping to integrate the different representational registers (Duval, 1993).

Eleven students, randomly selected from the 55 who answered the questionnaires, participated in this phase. They were asked, in particular, to determine whether several functions were continuous and differentiable, using DERIVE. The computer-based questions were similar to those given in the first questionnaire phase, so that the approaches with and without the technological tool could be compared, and the answers were classified using the same analysis categories from the first phase.

Prior to the activities, the students participating in this second phase, were given a two-session, 3 hour-workshop on the use of DERIVE, where they learned to use the main commands (with emphasis on commands such as *differentiate*, *sum*; and plotting commands including *Trace*, *Range* y *Zoom*). Students were also shown how to define functions by parts. They then practiced with activities related to the topic under study.

In a third session, students were asked to solve, using DERIVE, a series of questions. Students were asked to write down the DERIVE commands they used and what

they had done to arrive at their conclusions, as well as a justification for their answers. Like in the questionnaires, the computer-based questions referred to (i) the continuity of functions (the first question asked students to determine the continuity of two functions: one disconnected but continuous in its domain, and the second defined in parts); (ii) the differentiability of functions (three questions tried to determine students' use of the derivative-slope relationship, both algebraically and geometrically, and whether they realized that the derivative is not just an "algorithmic computation"); and (iii) the relationship between the derivative and the continuity of a function.

In particular, students were asked to determine the continuity and differentiability of each of the following functions: the first was the same function defined in parts that we presented in question 6 of the third questionnaire (see above). Most students, in the first phase, had considered that this function was differentiable, when in fact it is not. We expected students in this second phase to make use of the graph produced by the software, and notice the spikes it has; we were surprised when 7 of the 11 students disregarded the visual characteristics and claimed the function was differentiable everywhere. This indicates a lack of knowledge and understanding of the visual characteristics of a differentiable function.

The other functions were the following:

$$f(x) = \begin{cases} x^1 & \text{if } x \leq 1 \\ x^1 & \text{if } x > 1 \end{cases}$$

$$f(x) = \sum_{n=1}^{50} \cos(nx)$$

$$f(x) = \sum_{n=0}^5 \left(\frac{2}{3}\right)^n \cos\left(\frac{2^n}{3} \pi x\right)$$

The last two functions are functions whose graphs (which students can only produce using a technological tool) are very irregular and have many spikes; we wanted to see if students were able to analyze the geometric characteristics and determine the points of continuity and differentiability. These two functions have very similar graphs, but we noticed that students approached the two functions differently, with most of them claiming the first one as continuous and the second one as not: it seems that students were influenced by the complex algebraic representation of the latter one, and by its irregularly shaped graph.

### Discussion and Summary of Some Results

#### Findings from the Questionnaire Answers

- In relation to the continuity of functions defined in parts, it is interesting to note that many students tend to regard these functions as discontinuous (even when

they aren't) because of the way they are algebraically defined (in parts). This shows a lack of analysis and understanding of the definition of continuity, but also a non-reliance of the visual representation. It is also consistent, however, with the view that was held in the 18<sup>th</sup> Century by Euler and Lagrange, as explained at the beginning of the paper.

- In answering the second questionnaire, most students (80%) relied on the algebraic rules and algorithm for finding the derivative (even when the graph of the function was given); a result consistent with the works reviewed (e.g., Artigue, 1991, Orton, 1983). For many students, the reasoning appeared to be: *if the derivative can be computed, then the function is differentiable; if not, then it isn't*.
- But in answering the third questionnaire, most students (70%) used the continuity or non-continuity of a function for determining the differentiability. For instance, when considering the function  $f(x) = |x|$ , 23 of 41 students who justified their answers, used arguments based on its continuity (it is interesting that 8 of them answered that the function was discontinuous at the origin – see further below); and 18 of those students stated that the function was differentiable because it was continuous (an incorrect interpretation of the Fundamental Theorem – see below).
- 70% of students' answers refer to the Fundamental Theorem of Calculus. Some answers were: *"every differentiable function is continuous"*, or *"the first condition for a function to be differentiable, is that it be continuous"*. However, although students are familiar with this theorem, it is generally misunderstood, misused, or contradicted: in many cases students asserted that discontinuous functions were differentiable; and half of the students, see below, erroneously considered as valid the reciprocal theorem to the fundamental theorem:
- 49% of the students consider that if a function is continuous, then it is differentiable. Among the answers, were: *"the function is differentiable because it is continuous"*, *"the function is differentiable because every continuous function is differentiable"*; some even wrote *"a function is differentiable, if and only if, it is continuous"*. In other cases, the relationship is not explicitly expressed, but they refer to characteristics of continuity to justify the differentiability; for example, one student wrote: *"the function is differentiable because the function exists for every x"*.

In analyzing the influence of the different representational registers, we found that:

- In 95% of the cases, students give either "formal" arguments (making reference, either correctly or incorrectly, to theorems or definitions) or use the algebraic representation. There was thus a prevalence of the use of the algebraic register, as has been noted by Eisenberg & Dreyfus (1991).

- In determining the continuity, there was more use of visual arguments than for the differentiability (some arguments were that the graph had a hole, a jump, or else was uninterrupted). Whereas for determining if a function is differentiable, students tended to ignore the visual aspects. In fact, students constructed the graphs of the functions for less than a third of the cases – a result that contrasts greatly with the findings of Artigue (1991). Only in cases where the graph of the function was given, a few students (10%) used some visual aspects: they determined the non-differentiability by identifying spikes or saying that the curve was not smooth.
- However, even when the visual aspect was used, there was confusion between the notions of differentiability and continuity: some students claimed that a function was discontinuous if its graph had a spike: a characteristic of non-differentiability not related to continuity. This is consistent with the findings of Lara (1998) and Artigue (1991) who have found confusion in students between the characteristics of continuity and those of differentiability.

### Findings from the Computer-based Activities

It is important to begin by pointing out that the second phase did not turn out as we had hoped, since we had expected that the use of the software tool, with its visual and computing capabilities, would lead students to approach the problems in a different way. But the findings showed very little difference in the way the problems were approached and conceived with and without the use of technology. Nevertheless, we are cautious in emphasizing that this does not necessarily imply that the use of technological tools, such as DERIVE, cannot bring conceptual changes and a better integration of the different representational registers. We believe our results were mainly due to the way that the computer-based activities were presented (doing the same type of activity with paper and pencil, as was done with the computer, without incorporating a different pedagogical approach), the lack of experience in the use of the tool, and the lack of experience in using technology as an exploratory tool. These findings, however, do stress the importance that should be placed on the ways that new technologies should be implemented.

Despite all of this, we would like to summarize some of the findings from this phase. From their written work, we observed the following:

- for all the questions, the students gave the graphs of the given functions
- the continuity of those functions was almost always determined using the graph (some students even said: “*the function is continuous because it can be seen on the graph*”) with the main justifications given by students were that the graph did not have “jumps”, but also that the function was “defined for every  $x$ ”.

- in 63% of the answers, the differentiability of the functions was justified using the continuity, i.e. using, either correctly or incorrectly, the theorem “*every differentiable function is continuous*”.

The software tool was used to visualize the function and to determine the continuity, particularly for the last two functions (see above). On the other hand, when determining the differentiability, there was a lack of visual analysis and the same arguments given on the paper and pencil questionnaire were used (e.g. students used only the continuity of the function or its algebraic expression, to determine its differentiability): students did not take advantage of many of the useful tools provided by the software, such as the *zoom* command, and did not explore the graphs in any way. Thus, the students limited themselves to using the software only to construct the graph, ignoring the possibilities for exploring visual characteristics and carrying out a possible visual analysis.

The only observed advantage was in the fact that they could produce an accurate graph for each function, and this led to fewer mistakes when determining the continuity of the functions, than had been observed in the answers to the questionnaires.

But as in the first phase, it was observed that students lack a visual understanding of the concept of derivative, with a predominant use of the algebraic representation. In general, students tend to rely, whether correctly or incorrectly, on the continuity or non-continuity of the function for justifying the differentiability.

### Conclusions

The findings, from both phases, confirm one of our hypotheses: although students are familiar with the theorem: “*every differentiable function is continuous*”, they misuse it to determine the differentiability of a function, not recalling it properly or applying it in an incorrect way (they often use the invalid inverse theorem).

In terms of the use and influence of the different representational registers, we observed the following:

When determining the continuity of a function, students used both the visual and the algebraic registers, but there was a predominance of algebraic one, and their answers focused on the analysis of features from only one of the registers.

When determining the differentiability of a function, it was found that students do not use the graphical register, even when the function is given through its graph. A majority of students tend to focus only on the algebraic register (in the second questionnaire, only 2% gave answers based on visual characteristics, and only 0.5% used both registers).

However, when students were asked to determine both the continuity and the differentiability, there was a greater use of the graphic characteristics with some students referring to the smoothness of the graph or presence of “spikes”, even though the use of the algebraic register still dominated.

Thus, we observed a predominant use of the algebraic register, as has been found by Eisenberg & Dreyfus (1991), with a greater use of visual arguments when determining the continuity than when determining the differentiability.

In relation to the second phase, as is explained above, the use of the software tool did not produce the results we expected, since hardly any differences were detected between the approaches used with or without technology. We blame this on the way the computer-based activities were presented, but also on the school culture from which these students come, where software is only used as a tool for sketching a graph or making complex computations, and no emphasis is placed on the use of technology as a mathematical exploration tool.

As in the first phase, in the second phase we observed: a lack of understanding of the visual characteristics that help determine the differentiability of a function, and an over reliance on the continuity or non-continuity of the function for determining the differentiability. The only difference between the two phases was in the possibility to accurately sketch the graphs of the given functions, which did lead to fewer mistakes, particularly when determining the continuity. But even with this advantage, students did not exploit the possibilities offered by the software and for exploring the visual representations.

To summarize, we found that in general (i) there are confusions regarding the relationship and characteristics of the continuity and differentiability of a function (in accord with the findings of other researchers —e.g., Artigue, 1991; Dolores, 1998; Orton, 1983; Tall & Vinner, 1981); (ii) although students are familiar with the first form of the Fundamental Theorem of Calculus, it is generally misunderstood: it is used for determining the differentiability of a function, but it is not properly recalled and is used incorrectly; and (iii) there is a preference for the algebraic register of representation.

More importantly, there seems to be a disassociation in the use of the representational registers: they are seldom related or combined. This points to a lack of integration of, and appropriation of the concepts which, following Duval's theories, is not optimal for learning. There was some hope that the use of technology, which facilitates the use and exploration of the visual representational register, would help in this respect. But with only a limited use of the computer software, the computer-based activities did not change the results, since students approached the activities with the technology, in the same way as they did the paper and pencil ones. Therefore, clearly more research is needed in this last direction; in particular, in the way that technology is implemented.

# EXPLORING THE ROLE OF METONYMY IN MATHEMATICAL UNDERSTANDING AND REASONING: THE CONCEPT OF DERIVATIVE AS AN EXAMPLE

Michelle J. Zandieh  
Arizona State University  
zandieh@asu.edu

This paper discusses the role of metonymy in a structured derivative framework (DF). The DF consists of three layers of process-object pairs, one each for ratio, limit and function. Each of the layers can then be illustrated in any appropriate context, for example graphically as slope, verbally as rate of change or kinesthetically as velocity. Metonymy functions within this structure in terms of 1) the use of the contexts of the concept of derivative as paradigmatic examples, 2) the use of the layers of the concept of derivative to represent the whole concept (a type of individual metonymy) and 3) misstatements using part-whole or part-part references that could be described as metonymic but are mathematically inaccurate.

## Purpose and Objectives

The purpose of this research report is to explore how metonymy functions in both powerful and problematic ways in student reasoning about and understanding of the concept of derivative. The study of natural language structures such as metaphor and metonymy in the learning of mathematics is a growing research area (cf. English, 1997; Lakoff & Nunez, 2000). Since there has been much less work done on metonymy than on metaphor, this paper will add to that body of research. The concept of derivative is a particularly illustrative example because of the richness of its conceptual structure, and because the types of reasoning that occur in this example will have parallels in other contexts.

## Theoretical Perspectives

### Metonymy

Lakoff and Johnson (1980) spend one chapter of their book, *Metaphors We Live By*, focusing on metonymy. They describe metonymy as occurring when we use “one entity to refer to another that is related to it” (Lakoff & Johnson, 1980, p. 35). This may mean that we use a part to stand in for the whole as in their example, “I’ve got a new *set of wheels*” (Lakoff & Johnson, 1980, p. 36). Here the phrase “set of wheels” stands for the whole car. In other cases we use a part of a conceptual structure to refer to another part of the same conceptual structure. For example, “We need a better *glove* at third base” (Lakoff & Johnson, 1980, p. 38). Here the glove stands for the user of the glove.

Lakoff and Johnson (1980) point out that although metonymy is primarily a referential device, it also influences understanding. There are many parts that might be

chosen to represent the whole or to represent another part of a conceptual structure. These choices are not arbitrary. Using one part (set of wheels) to stand for the whole (car) draws attention towards one part of the conceptual structure and away from other parts. This usage may be a choice of the speaker, in which case it shows her/his focus. On the other hand it may be that the usage is conventional and that the speaker could have chosen no other part and been understood. For example, "I've got a new set of windows," would not convey the appropriate meaning. However, the choice of letting the wheels stand for the car is not neutral; it demonstrates a lens through which our culture understands the relationship between these entities.

The preceding examples of metonymy from Lakoff and Johnson (1980) are of the type that Presmeg (1997) calls "metonymy proper." She states, "Metonymy proper [occurs when] a salient or related entity is taken to stand for another entity" (Presmeg, 1997, p. 270). She then describes a second type of metonymy where "one element for a class may be taken to stand for the whole class" (Presmeg, 1997, p. 271).

These two types are both emphasized in Lakoff's (1987) book, *Women, Fire and Dangerous Things*. Lakoff states that a metonymic model consists of two entities A and B that are in the same conceptual structure. B is either part of A or closely related to it. "Compared to A, B is either easier to understand, easier to remember, easier to recognize, or more immediately useful for the given purpose in the given context" (Lakoff, 1987, p. 84). The metonymic model describes how B is used to represent A in the conceptual structure. Metonymic models may model a single entity or a category.

Metonymic models of categories are equivalent to the second type of metonymy referred to by Presmeg (1997). They take an example or submodel and use it to stand for the entire category. These are what Fischbein (1987) calls paradigmatic models. Paradigmatic models describe our tendency to see a whole class of objects or an entire concept through the knowledge of particular examples or a submodel that exemplifies the concept or class. Not all examples are paradigmatic models, only those that provide enough variety of features to be representative of the entire group, yet are simple enough to be easy to use in reasoning. These representative examples are sometimes called exemplars or prototypes. For the concept of derivative, velocity is a particularly important example, a paradigmatic model of the concept of derivative in a physical context. Velocity is an exemplar because it is an extremely familiar phenomenon for which we have additional natural language structure. For example, increasing velocity is called acceleration and decreasing velocity is called deceleration.

If the model, B, is an example of the original category or concept, A, then we may call B a paradigmatic model. If the model, B, is a part of A that is not an example, I will call this *individual metonymy* to emphasize that the metonymy refers to an individual conceptual structure rather than a collection of examples of a category or concept.

One further example of individual metonymy provides insight into the derivative concept. Lakoff (1987) uses the example of going to a party. The trip consists of

a precondition that you have a way to get to the party, embarkation, the travel itself, arrival and an end point. If someone asks you how you got to the party, you would not recount the entire scenario. You might say, "I drove", letting the center stand for the whole. Alternatively you might say, "I have a car", letting the precondition stand for the whole.

Functions (including the derivative function) have a structure similar to a trip. There is a domain of starting values, a rule or correspondence, the calculation of which is analogous to traveling, and an end point or value of the function for each starting value. We sometimes name a function by referring only to its rule or correspondence without reference to its domain or range. This short hand is a type of individual metonymy, letting the part stand for the whole. The short hand also provides an emphasis on one aspect of the whole over other aspects.

It must be remembered that the existence of a metonymic (part-whole or part-part) relationship between two entities is not enough to guarantee that these entities may be properly referred to using the same word or that the part may properly be used to stand in for the whole. The use of the same word for both the part and the whole is motivated by the part-whole relationship, but is not implied by it. If a student or novice uses a part to stand for a whole (or another part) in a way that would not be considered conventional or proper usage in her/his culture, then this may be called a misstatement. For example, a student might shorten the phrase "the derivative is the slope of the tangent line at a point" to "the derivative is the slope," a phrase which is considered appropriate usage by the mathematical community. On the other hand, the student shorten the phrase to "the derivative is the tangent line," a phrase which would be considered mathematically incorrect. Examples of such misstatements for the concept of derivative will be discussed near the end of this paper.

Lakoff (1987) argues that we can determine the structure of a concept by examining the language we use to talk about the concept. His case study is the concept of anger. He and his colleague Zoltan Kovecses began with a systematic study of the expressions we use in English to talk about anger based on methods developed in Lakoff and Johnson (1980). Lakoff (1987) argues that "there is a coherent conceptual organization underlying all these expressions and that much of it is metaphorical and metonymical in nature" (p. 381). This notion was the impetus for my developing the structure of the concept of derivative that is in the next section (and previously described in more detail in Zandieh, 1997, and Zandieh, 2000). Like Lakoff (1987), I began the process by analyzing all the ways that I heard students and faculty talk about the concept of derivative at the freshman calculus level. Even though I did not follow Lakoff's method in detail and used many influences from the mathematics education literature that would not have applied to his case study, the notion of metaphoric and metonymic models was implicit in its development and in my use of it for analysis. In this paper I will make more explicit some of the metonymic connections.

However, first I will give an overview of the derivative framework without regard to metonymy.

### Derivative Framework

The derivative framework, DF, has two main components: multiple representations or contexts and layers of process-object pairs. The concept of derivative can be represented (a) graphically as the slope of the tangent line to a curve at a point or as the slope of the line a curve seems to approach under magnification, (b) verbally as the instantaneous rate of change, (c) physically as speed or velocity, and (d) symbolically as the limit of the difference quotient. Many other physical examples are possible, and there are variations possible in the graphical, verbal, and symbolic descriptions.

Consider the formal symbolic definition of the derivative:

$$f'(x) = \lim_{h \rightarrow 0} \frac{f(x+h) - f(x)}{h}$$

The derivative of  $f$ ,  $f'$ , is a *function* whose value at any point is defined as the *limit* of a *ratio*. I will call these underlined aspects of the concept of derivative (ratio, limit, function) the three “layers” of the framework. At this point we may combine the layers and the contexts or representations to form a matrix outlining the structure of the concept of derivative (Figure 1). Although only four columns are named specifically, there can be many other columns, one for each situation in which there is a functional relationship for which one may discuss the concept of derivative.

Each empty box in the matrix represents an aspect of the concept of derivative. For example, the box in the ratio row and the graphical column represents the slope of a secant line on a graph of the function whose derivative we are concerned about. More details about the layers in terms of slope, velocity and the difference quotient may be found in Zandieh (2000).

Mathematically it is clear that the concept of derivative involves a ratio, a limit and a function. However, thinking of these as “layers” comes out of my thinking about Sfard’s (1992) framework of processes acting on previously established objects. Her notions of operational and structural conceptions add a third dimension to my framework. Each empty box in the matrix in Figure 1 may denote either a structural or operational understanding which I denote as a process or object understanding for each square in the matrix<sup>1</sup>.

### Methods

The data reported here are from five semi-structured interviews conducted with each of nine high school students during their senior year Advanced Placement

|                      | Contexts  |        |              |            |          |

*Figure 1.* Outline of the framework for the concept of derivative.

(AP) calculus course. This data is part of a larger study reported in detail in Zandieh (1997).

For the data analysis, transcripts of student interview responses for each of the five interviews were color-coded for each of the contexts and layers. In addition, connections a student made between contexts and student misstatements were noted on the transcript. Most of the coded transcripts were then transformed into a tabular format similar to Figure 1 (Zandieh, 1997; Zandieh, 2000). These tables documented and were used for further analysis of students' use or lack of use of specific contexts, layers and process-object structures. In addition, a place on the table was designed to note misstatements.

### Result and Discussion

There are a number of ways in which metonymy occurs in student reasoning with the context of the derivative. This section will discuss four issues: 1) general metonymic structures that occur within this framework and that would occur in many other mathematical settings, 2) metonymic use of the contexts of the concept of derivative as paradigmatic examples, 3) metonymic use of the layers of the concept of derivative to represent the whole concept (a type of individual metonymy) and 4) misstatements using part-whole or part-part references that could be described as metonymic but are mathematically inaccurate.

### **Metonymy Embedded in the Derivative Structure**

As Presmeg (1998) notes, whenever we use a letter to represent a set of numbers, then we are using metonymy. Lakoff and Nunez (2000) refer to this as the Fundamental Metonymy of Algebra. Another fundamental metonymic process is the chaining of signifiers (Presmeg, 1997, 1998) which is closely related to the reification which occurs within each process-object layer of the DF and allows for the chaining of the layers. In addition, metonymy occurs when students do not reify an operational “process” conception into a structural “object” conception but use a pseudostructural conception (Sfard, 1992) or pseudo-objects (Zandieh, 2000) to stand for or stand in the place of the incompletely understood conception. This allows for some chaining of the layers even when each layer is not well understood.

Consider a student who says that the derivative is “the instantaneous velocity.” This phrase may represent for the student a complex set of processes including a ratio of distance over time and a limiting process to convert average velocities over specific times to an instantaneous velocity which occurs at a moment, i.e. over 0 time. Thus the student uses the brief phrase to metonymically stand for the chaining of the first and second process-object pair layers of the derivative concept. On the other hand the student may only mean that the derivative is the speed that the car is going at a moment in time, without any knowledge of the underlying mathematical structure of these concepts. The notion of speed at a moment of time can be understood experientially even by very young children. In either case, the student’s knowledge of instantaneous velocity can be used to help the student understand the velocity function as a speedometer that provides a speed value for any moment in time. This chaining of the second layer to the third layer takes only the metonymic representation which stands for the first two layers, whether or not the first two layers are fully or only partially being represented.

### **A Context Stands for the Derivative: Paradigmatic Examples**

One way in which we see a context as standing for the whole derivative concept is when we ask students to display a personal concept definition (Vinner, 1991) by asking, “What is a derivative?” Another way of noting metonymic use of particular contexts is in noting what context a student reaches for when asked to reason about the concept of derivative in a variety of settings.

The nine students in this study had a wide variety of preferred contexts at the time of the first interview. Some students mentioned slope and rate of change most often while other students mentioned velocity or the process of taking the derivative more often. By the final interview all but one of the students mentioned slope and rate most often. These results may be influenced in this study by the questions that the students were asked and by the instruction the students were given. However, given that the questions were broad and wide ranging and that the instruction was fairly standard, I believe that there is also a more fundamental reason for this result.

The best paradigmatic models are familiar, well understood and easily applied to understanding the derivative as a whole. In the first interview, students do not have a very complete understanding of derivative so they mention models that are most familiar. As the students broaden and deepen their knowledge of derivative, the students become more familiar with other possible models and applicability becomes more of an issue. Students see that rate of change is a general phrase that may be used in many different situations without as much explanation or interpretation as a specific context such as velocity. Slope continues to be a model that is particularly effective for interpreting other contexts because of the special characteristics that graphs provide. In particular, graphs are useful as synoptic, global representations.

However, not all students who mention slope often can always use it appropriately. Ingrid, does not see that her answer to "what is a derivative?" need play a strong role in her reasoning about derivative in other contexts. The most striking example of this occurs in her second interview. In both of the first two interviews Ingrid repeatedly states that the derivative is "the slope of the tangent line." In the second interview she is asked to give a 'real world example.' Her example is a slightly faulty example regarding change in volume over time, which she represents as  $dV/dt$ . When asked how the derivative plays into her example she indicates the  $dV/dt$ . Then the interview asks whether slope is related since she has said that the derivative is slope of the tangent line. Her answer is that it is not, and then, "Are all derivatives that? Slope?" It hasn't occurred to her that each context in which we use derivative should have an isomorphic structure with each other context. In natural language it is common for a word to refer to many things which are not isomorphic in structure, nor even have any one thing in common to all examples, but rather that the examples have something in common with each other. This is the notion of family resemblances (Wittgenstein, 1958; Rosch & Mervis, 1975).

Mathematical structures, unlike natural language structures, are organized more rigidly. We expect to have a definition for a mathematical term like derivative and to be able to determine immediately whether something fits by whether it has the same structure as the definition. My data indicates that although many students do see the parallel structure across contexts, they are least likely to use the formal symbolic context as the primary context that they reason from. The best students can reconstruct the formal definitions from the structure of their informal understanding and the worst students ignore (or memorize and then ignore) the formal definition completely.

In summary, each of the contexts of the concept of derivative has the potential to be a metonymic model or paradigmatic example for the concept as a whole, but some contexts are much more useful than others for this purpose. As we saw with Ingrid, the use of a paradigmatic example such as slope does not mean that a student understands that there is an isomorphism between that example and the other contexts for derivative. An exploration of how a student views and uses the potential isomorphisms

between pairs of contexts would be a study of metaphoric rather than metonymic models.

### **A Layer Stands for the Derivative**

The first layer of the derivative concept is the average rate of change, which cannot by mathematical convention be called “the derivative.” The second and third layer can each be called “the derivative.” We can see Ingrid’s confusion with this issue when she is asked a subtle question, “Is the derivative a function?” Her response: “No ... It’s just a slope. It’s not like  $y$  equals something. ... cause you can’t graph a slope. ... Or you can’t graph a limit. But then ... Like on a test, ‘This is the graph of the derivative.’ I guess it has to be. It could be a function.”

From Ingrid’s response we can see that she is struggling to clarify the conflict between calling something a derivative that is a slope or limit value (second layer) with something that is a graph or equation of a function (third layer). Here we see metonymy play out in two different ways. First, the phrase “the derivative” is being used to stand for a longer phrase “the derivative value” or “the derivative function.” If a longer phrase had been used as opposed to a metonymic short cut (part of the phrase to stand for the whole phrase), then there would have been no confusion. A second metonymic relationship is that between the two meanings that can be associated with “the derivative.” The derivative function is a complex process like the trip described in the Theoretical Perspectives section. The derivative value is just one part of the trip, the destination for one starting value. So the second layer derivative is a part of the third layer derivative whole. Lakoff (1987) explains that metonymic relationships are common in these cases. “Related meanings of words form categories and the meanings bear family resemblances to one another” (Lakoff, 1987, p. 12)

### **Metonymic Misstatements**

The two most common misstatements in my data are “the derivative is the tangent line” and “the derivative is the change.” One way of viewing these metonymic misstatements is purely syntactic. An example with slope was provided in the Theoretical Perspectives section. A second example is the phrase “instantaneous rate of change”. If a student shortens this phrase to say that “derivative is a rate,” then the statement is acceptable. However, if the student says, “derivative is a change”, then the statement is not mathematically accurate. So some cases of letting part of the phrase stand for the whole phrase are considered acceptable by the mathematical community whereas other metonymic short-cuts are not.

I will provide two examples for rate of change and then two for slope of the tangent line. In each case the first of the two examples is primarily syntactic whereas the second example has a more conceptual focus.

In the first interview, Carl makes several syntactic misstatements involving rate of change. Although he does state that the derivative is the instantaneous rate of change

in the following sequence, his explanations focus more on the derivative as change instead of rate of change. Carl says, "If you were to take the derivative, you'd end up with  $dx/dt$  or  $\Delta x$ . The change in  $x$  over time. So that's basically like  $\Delta x$ ." When asked for clarification, Carl explains further, "When you take the derivative of something you find the change in that. ... And it changes the equation from how much water is in it to how much it's changing at that instant, how much is leaving or going in at that instant. It's the instantaneous rate of change."

In the fifth interview, two students make a conceptual metonymic error. Each student is told that  $f$  is a function that gives the outside temperature at a given time. The student is then asked to interpret  $f'(3)=4$  and later  $f'(3)=4$  for  $0 \leq x \leq 3$ . Both Carl and Derick initially interpret  $f'(3)=4$  to mean that the temperature changes instantaneously by 4 degrees at the 3 hour mark, instead of the correct interpretation that the rate of change of temperature is 4 degrees per hour. Each of these two students fail to see their error until they make an analogy with distance and velocity. Derick makes the connection on his own; Carl responds to the interviewer's suggestion.

Carl and Derick's initial error is that they let the change (per one unit) stand for the rate of change. Instead of taking a part of the phrase for the whole phrase, they take a part of the concept, the change in output values, for the whole concept, the change in output values divided by the change in input values. Often we calculate average rate of change or approximate instantaneous rate of change using one-unit intervals, which obscure the role of the denominator. Even in stating that the derivative is 4 the nature of the derivative as a ratio is implicit.

Another type of conceptual individual metonymy occurs when discussing slope of the tangent line. Consider the complex process by which we describe the derivative at a point graphically. Whether we describe a sequence of secant lines approaching the tangent line at a point or we describe zooming in on a point until the curve appears to be a line, in each case the derivative is the slope of that line. However, a student who has focused on this image may say that the derivative is this whole process or that the derivative is the most obvious image or endpoint of this graphical process, the tangent line. The slope is implicit in both graphical images, but the tangent line is explicit, visible and thus more easily remembered. Even without the idea of a limiting process a student may remember a single image, a curve with a line tangent to it, when asked what a derivative is. Again one might pick up on the tangent line as the explicit, visual representation of the derivative instead of remembering that the derivative is the slope of that line.

Carl provides syntactic metonymic examples for slope of the tangent in the following. When asked if derivative is related to slope, Carl says, "Derivative is the tangent line to the function," before correcting this a few lines later to "The derivative is the slope of the tangent line to the graph." When asked if derivative is related to line or linear, Carl again confuses the two, "It's the line, the tangent line. It's the slope of

the tangent line is the derivative, so the tangent line to the graph is the derivative as well.”

Grace’s misstatements are subtle and in the end a bit more conceptual. She says that the derivative is “tangent to the slope at a given point”, “tangent of your slope” and “tangent of slope”. At first these statements sound like a simple transposition of words. That these statements refer to the tangent line to the curve (slope) is made more clear in Grace’s second interview. In the second interview she says that the derivative is “tangent of the slope” and when questioned clarifies by saying “the line that’s tangent of the slope”. She also says that the derivative is a line when asked to relate derivative to line or linear. “I mean your derivative is like a line. I guess that’s kind of the context, isn’t it, of derivative. When you have a point and you’re finding tangent lines getting closer to that point, approaching that point.”

In each of these examples, inappropriate metonymic connections seem to come naturally to these students. The students at times also seem to believe both versions of the statements, e.g. that the derivative is the slope of the tangent line and that it is actually the tangent line itself. The two contradictory ideas may be compartmentalized by a student so that the student does not notice the contradiction. However, even without compartmentalization, a student may think that it is legitimate to use derivative to mean both slope of the tangent line and the tangent line itself. If “the derivative” can refer to both a value and a function, perhaps derivative could refer to both slope value and tangent line. Slope and tangent line have a metonymic part-whole relationship that is not too unlike the derivative value to derivative function relationship.

### Conclusion

As we have seen, metonymic models may function both in powerful and problematic ways for students as they come to understand and work with a complicated concept such as the derivative. It is the goal of this paper to illuminate and clarify these relationships in the hopes of providing insights to teachers and researchers.

### PSEUDO-EMPIRICAL ABSTRACTION IN ADVANCED MATHEMATICS

Lara Alcock  
Rutgers University  
lalcock@rci.rutgers.edu

Adrian Simpson  
University of Warwick  
A.P.Simpson@warwick.ac.uk

This presentation is based on one student's attempts to argue that all convergent sequences of real numbers are bounded. It is suggested that his approach may be indicative of learning via pseudo-empirical abstraction. This leads to questions about the relationship between the objects constructed through this type of learning and their formal mathematical counterparts.

This presentation is based on interviews with students during the seventh week of a first course in Real Analysis. During these interviews, students were required to justify the statement that if a sequence is convergent, it must be bounded.

Some students answered this by sketching a convergent sequence and generalizing. This may be seen as a concept-image based argument (Tall & Vinner, 1981). For such students, the image is representative of the set of convergent sequences; in their work, such objects exist on a perceptual basis (Tall, Thomas, Davis, Gray, & Simpson, 2000).

Other students reason by introducing the definition of convergence and making deductions from this. In their work, the set of convergent sequences exists on a formal basis (Tall et al., 2000.), and their arguments apply to all the objects in the defined set.

Here, we consider the work of a student for whom the set of convergent sequences does not appear in the argument at all.

Xavier begins by introducing elements from the definition.

*X: Isn't it something to do with that... $a_n$  minus  $l$ , don't you remember?*

Although this sounds rather instrumental, he gives a reasonable approximation to the entire definition, albeit not a logically well connected one.

*X: Er, the term in the sequence, minus the limit...the modulus of that is less than epsilon where epsilon...is...any real number...and  $n$  is beyond any big  $N$  in the sequence...*

Although Xavier is not fluent in speaking about this definition (in the next excerpt he says "e" when he means "epsilon" and confuses his " $l$ " for the digit "1"), he appears to be on his way to making a sensible argument.

*X: ... And then if you get rid of the modulus sign, you can write that as minus epsilon is less than  $a$  to the  $n$  minus one, is less than epsilon, and that can be*

rearranged so that  $a$  to the  $n$  is less than,  $\epsilon$  plus one, but it's also greater than one minus epsilon...

However, from this he concludes:

X: So therefore  $a$  to the  $n$  is bounded above and below, and therefore this is the definition for the convergent sequence. So it converges.

It appears that once he begins working with the definition, Xavier becomes side-tracked into a routine of showing that a given sequence is convergent. This persists when the interviewer asks him what happens for the terms before "big  $N$ ".

X: Erm, well they'll be...erm, the modulus will be bigger than epsilon. So you've got to go far enough along, so that you're less than epsilon.

This last statement also assumes that for a given epsilon, all the terms before the associated "big  $N$ " must be further from the limit than this epsilon. Hence, while his argument initially looks more "mathematical" than those using concept images, he does not have a solid understanding of what objects belong to the set.

It would be easy to dismiss this as rote learning, but we believe that this would do Xavier an injustice. Students who did attempt rote learning could not recall even parts of the definition, much less manipulate an almost complete version (cf. Moore, 1994). In Xavier's case he began appropriately, but his work does not seem to have any link with the set of convergent sequences, either as conceived by Xavier as an individual, or as a formal set delimited by the definition.

Instead the definition was associated with a process. This, for us, brought to mind the idea of pseudo-empirical abstraction, that is, the construction of new mental objects not from perception, but from repeated experience with actions upon others (Asiala, Brown, DeVries, Dubinsky, Mathews, & Thomas, 1996). Perhaps this case could be characterized as pseudo-empirical abstraction in progress, the action being that of demonstrating that a sequence is convergent by showing that it satisfies the definition.

If this characterization is reasonable, then this raises some interesting questions regarding how Xavier's learning will proceed. If he encapsulates this process to form an object, will this object be the definition? If so, will this then be available for proof problem like this one? Will it ever be associated with a category containing the individual convergent sequences? Does this matter? Could Xavier learn to take advantage of image-based thinking, in which the range of these objects can be more apparent? Should he be encouraged to?

It is hoped that this presentation will generate discussion of these issues.

**STUDENTS USE DIFFERENT REPRESENTATIONS FOR THE  
CALCULUS DERIVATIVE FUNCTION:  
TWO CONTRASTING CASES**

Leslie Aspinwall  
Florida State University  
aspinwal@coe.fsu.edu

Kenneth L. Shaw  
Florida State University  
kshaw@mail.pc.fsu.edu

Traditional instruction in calculus concentrated primarily on manipulation of symbolic or analytic representations while reform efforts over the past decade have promoted an understanding of both analytic and graphic representations of functions and derivatives. For example, graphic representations convey mathematical information visually, whereas expressions represented symbolically can be easier to manipulate, analyze, or transform. Instructional representations have been treated as a desired *end* in mathematics curricula; students' progress has been measured by how closely they are able to express their internal representations as accurate manifestations of instructional representations. Our work differs in that external representations as an instructional activity constitute a *starting* point for students' mathematical constructions. In this paper, we report on the development of understanding of two students for the calculus derivative function and the implications for learning and teaching calculus.

Generally, the ability to visualize in mathematics is thought to be advantageous, but Aspinwall, Shaw, and Presmeg (1997) reported on the case of a calculus student whose vivid mental images hampered his ability to think about the graph of an algebraic function with infinitely increasing slopes. Moreover, studies (e.g., Vinner, 1989; Tall, 1991) have consistently shown that students' understanding is typically analytic and not visual. Two possible reasons for this are when the analytic mode instead of the graphic mode is pervasively used in instruction, or when students or teachers hold the belief that doing calculus is skillfully manipulating symbols and numbers. It is clear from the literature (e.g., Lesh, Post, & Behr, 1987; Janvier, 1987; NCTM, 2000) that having multiple ways – for example, graphic and analytic – to represent mathematical concepts is beneficial.

In this paper we report on the development of understanding of two students for the calculus derivative function and the implications for learning and teaching calculus. Our work is framed by Krutetskii (1976) who distinguished among main types of mathematical processing by individuals: analytic, geometric, and harmonic. A student who has a predominance toward the *analytic* relies strongly on verbal-logical processing and relies little on visual-pictorial processing. Conversely, a student who has a predominance toward the *geometric* relies strongly on visual-pictorial processing and has above average verbal-logical processing. A student who has a predominance toward the *harmonic* relies equally on verbal-logical and visual-pictorial processes.

Our work also is framed by the view that posing and analyzing rich tasks for students provides windows into their thinking with ramifications for curriculum and instruction. As a result of observations of what students say and write, and how they represent mathematical situations, researchers make decisions about appropriate ongoing investigations. Generally, subsequent tasks are designed to clarify or validate early assertions. Here, we illustrate the contrasting thinking processes of Tim, whose representational scheme is predominately geometric, and Lil, whose representational scheme is predominately analytic.

The qualitative methods for the study consisted of analyses of participants' responses to tasks designed to probe their different understandings of the calculus derivative function. The framework for the analyses is a theoretical perspective we assembled that is inspired by research in both mathematics education and cognitive psychology. The theory generated, interpreting these differences, is explicated by references from the data to these perspectives in the literature. We explored the students' thinking on twenty tasks, one of which is depicted in Figure 1. For this task, students

Figure 1.

were directed to "Draw the graph of the derivative of the function whose graph is shown." The students were asked to explain their thinking. Additional tasks will be shown during the presentation.

This research is a component of a larger line of research aimed at a better understanding of how students learn elementary calculus viewed through their personal and idiosyncratic representations of the derivative function. The data sets consist of a large collection of videotapes of students working on tasks, verified transcripts of those videotapes, researchers' field notes, students' work, and researchers' journals. Analyses of videotaped sessions included coding of events, triangulation of qualitative data, and identification of distinct strands. Task design and implementation were critical: a limited number of tasks were created before data collection began; the vast majority of tasks were the result of prior tasks designed to clarify or validate early assertions. Frequently, tasks were revisited to determine if students thinking had changed as a result of subsequent tasks. The data were recorded over a period of six months as the students met weekly with the researchers.

## Results

Tim's and Lil's instructional experiences in Calculus I and II were similar, but their unique, contrasting representational schemes for the derivative function were quite different. Tim processed information by virtue of analysis of his graphic representations of the derivative function. Tim did display an ability to combine his graphic schemes with an increasingly robust analytic representation that he used to validate his conclusions; however, overall, he showed a predominance toward a geometric type of processing.

Lil, who tends to process information analytically, made her sketches of the derivatives for these tasks by first translating to analytic representations. Lil appeared not to be comfortable with constructing a graphic connection between the slopes of tangent lines to the graph of a function and the behavior of its derivative. Thus she rarely used such constructions. She produced sketches and written and verbal responses to questions that revealed her facility with analytic representations.

Tim's and Lil's work, and their descriptions of their work, for the task in Figure 1 are typical examples of the differences in their thinking. Lil's preference for analytic representations in the form of equations soon became evident. She began by inferring that the graph in Figure 1 was  $y = x^2$ . She then computed  $y' = 2x$  as its derivative. Using analytic representations in the form of equations, she calculated ordered pairs [(1,2) and (2,4)] for the function  $y' = 2x$  and produced the drawing shown in Figure 2. Lil's procedures suggest that her cognitive structures for the derivative function are predominately analytic.

Analysis of Tim's thinking suggests he tends toward Krutetskii's geometric type of processing. For the task in Figure 1, he worked quickly and explained how he produced the drawing in Figure 3 based on his estimates for slopes: "It's [the slope is] a greater negative here [pointing to the negative part of the x-axis of Figure 1], and then it [the slope] slowly becomes more positive [meaning less negative] near 0. As we go to quadrant I over here, from quadrant II, it [the slope] goes from 0 to more and more positive values. So, I knew the line [graph of the Derivative] had to go from quadrant III to quadrant I and on up [as seen in Figure 3]."

Figure 2.

Figure 3

Tim's drawing of the derivative as a curved line from quadrant III to quadrant I illustrates his preference for using a graphic representational scheme, typical of individuals with an ability and a preference for geometric processing. In his work he made no attempt to describe his work analytically, for example, by inferring the function  $y = x^2$ , computing  $y' = 2x$ , and determining ordered pairs to complete the graph of the derivative.

### Conclusion

Although Tim and Lil utilized two different types of representations, we believe students develop mathematical power by learning to recognize an idea embedded in a variety of different representational systems and to translate the idea from one mode of representation to

another. A positive result of multiple instructional representations of concepts is that students learning to present their representational schemes will reveal aspects of their understanding

that might not otherwise emerge. Otherwise, students are merely confronted with and must construe a teacher's representational preference, and the task for students becomes one of memorizing the presentation rather than learning to select or create representational schemes for problems they are trying to solve.

## TO STUDY MATHEMATICS IN AN ENGINEERING PROGRAM

Thomas Lingefjärd  
Chalmers University of Technology  
& Göteborg University

A significant number of students who study mathematics after graduating from the gymnasium in Sweden are students in engineering programs. Typical of the engineering programs at the Chalmers University of Technology is that most first-year students take courses in unfamiliar areas of mathematics. For many students, meeting with abstract or linear algebra is like a culture shock. An interuniversity project, CDIO,<sup>1</sup> contains several assessment efforts, including the study reported here, which should be seen as an attempt to describe how engineering students in their first linear algebra course apprehend the organization of the course, the teaching, the course goals, the assessment procedures, and the course context.

### Introduction

Several researchers have attempted to categorize advanced mathematical thinking. Robert and Schwarzenberger (1991) describe in the following statement how learning in advanced mathematics is different from learning in elementary mathematics:

There is a quantitative change: more concepts, less time, the need for greater power of reflection, greater abstraction, fewer meaningful problems, more emphasis on proof, greater need for versatile learning, greater need for personal control over learning. The confusion caused by new definitions coincides with the need for more abstract deductive thought. Taken together these quantitative changes engender a qualitative change, which characterizes the transition to advanced mathematical thinking. (p. 133)

It is unclear from this statement how much of the difference is due to the mathematical content itself and how much to the way the courses are taught. To date, there seem to be no agreement in the community of mathematics and mathematics education on what advanced or elementary mathematical thinking really is. In *The Nature of Mathematical Thinking* (Sternberg & Ben-Zeev, 1996), Sternberg wrote in the culminating chapter, "In reading through the chapters of this volume, it becomes clear that there is no consensus on what mathematical thinking is, nor even on the abilities or predispositions that underlie it" (p. 303).

### The Algebra Course

The algebra course in the mechanical engineering program is built around a common core of linear algebra, including such concepts as vectors, matrixes, determinants, complex numbers, polynomials and algebraic equations. The course is a 7-week course, organized into what are called "theme weeks," with each week organized as follows, beginning with Day 1 on a Thursday:

- Day 1: The instructor gives an introductory 2-hour lecture, with an introduction to the theme—the study domain for the rest of the week—the objectives and goals, examples, and important theorems and relations.
- Days 2 and 3: The students work in groups of 4 within a section of about 30 students and 1 teaching assistant. The teaching assistant serves as a coach but can also demonstrate further examples in the content domain to the whole section. So-called huge questions are left for the post-lecture.
- Day 4: The students are examined on the week's work.
- Day 5: The instructor gives a concluding post-lecture for all students.

An important feature of the organization is that the students work in small groups, thereby allowing discussions and, according to the instructor, prepare for “learning by explaining to someone else” but also for stimulating group discussions. Another important idea is the two assignments each week; these are larger problems on which the students are examined on Day 4, both orally and in writing. The students are also encouraged to keep a journal during each theme week in order to reflect on their learning. The journal is counted as part of the assessment. The 14 homework problems (2 every week) and the 6 journal entries (journal entries every week but one) yield a maximum of 20 points. To pass the course, the student needs to have at least 12 points from this part of the assessment. In addition, the student needs to get at least 12 points on the 30-point final exam.

### **The Students**

In the fall of 2001, 189 students were admitted to the mechanical engineering program at Chalmers. They ranged in age from 19 to 33 years, with a median age of 22 and a mode of 20. The median value of their gymnasium grade was VG (well passed; i.e., 4 on a 5-point scale). Thirty-two were women, and 157 were men. They began their studies in mathematics with the algebra course, which started with an introduction on September 4 and ended with the final examination on October 25. Thereafter the students continued the program with courses in analysis and classical mechanics.

### **Method**

The study was conducted with two surveys, interviews, and lecture hall and classroom observations. The survey instrument was based on an indicator instrument from Australia called Course Experience Questionnaire (Johnson, Ainley, & Long, 1996) and given during and after the algebra course. The interviews were conducted with volunteers who responded to a general request for students who would like to participate in an interview regarding their studies in mathematics. Fifteen students contacted me and came to the first round of interviews, one at a time. Ten students came to the second round of interviews, seven came to the third interview, and five were interviewed a fourth time. The first interview began with me providing information about

the CDIO project; then I asked each student about his or her rationale for studying at Chalmers, the time spent on studies, the way the student experienced studying mathematics at this level in general, and so forth. The interviews also included conceptual and technical questions about linear algebra. Finally, we talked about the algebra course in a more detailed way. The students were also asked to draw conceptual maps to describe how they saw linear algebra concepts linked together. All this happened during the first interview, the following interviews concerned the analysis course, and the course in classical mechanics although we always discussed the algebra course as well. I also sat in on lectures in algebra (as one “student” among all the other students) and visited classroom activities.

### Results

A final report containing the full set of surveys, responses to each item, interviews, and student results for linear algebra, analysis, and mechanics should be available by the end of 2002. The results of the study need to be seen in relation to one another, but as a single and isolated result from the surveys, there was a trend for students’ beliefs in their generic skills to decrease during the course. The fact that as many as 40 % (72 out of 180) of the students failed to pass the first exam was probably responsible for much of the deterioration in confidence.

Another interesting result concerns the students’ opinion of the reflective writing assignment. During the course there was a polarization of students’ opinions about the usefulness of reflective writing. After the course, more students expressed the opinion that they saw no benefit whatsoever in reflective writing when learning mathematics.

The affective part of the interviews revealed many surprising findings, together with some more expected ones. As with the surveys, there is no room here for a detailed report.

The interviews also revealed rather surprising gaps in the students’ knowledge of linear algebra. Only a third of the students could, for instance, describe the concept of *rank*, and no one was prepared to give an answer to the somewhat challenging question, “What is linear algebra?” After some time I usually added the questions: “Is it a formal game?” “A set of abstract structures?” “A language?” “A tool with which to investigate natural phenomena?” The great majority of the students selected the last alternative. I find it intriguing to see the difficulties these students experienced when trying to see an overall picture and how they apparently have chosen to study only to learn facts and procedures.

### Conclusion

Given the efforts by mathematicians and mathematics educators in the CDIO project to give this algebra course a greater focus on understanding, the results of this study were disappointing. Linear algebra is hard to learn and has for years had the reputation of being one of the principle obstacles in introductory university mathematics.

During the sixties, at a conference in Zürich, I made the acquaintance of a charming old man who was none other than Plancherel – of Plancherel's theorem – and who, during a very interesting conversation, insisted on the fact that of all the teaching he had done that of linear algebra seemed to be by far the most difficult for students to understand. Thirty years later the situation does not seem to have changed very much and we can assure Plancherel that he is in good company. (Revuz, 2000, p. xv)

Nevertheless, this situation is not satisfactory, and educators and researchers must continuously work on improving the teaching, learning, and assessment of linear algebra to increase its accessibility to more students.

### Endnotes

<sup>1</sup>CDIO is a project in cooperation between Chalmers University of Technology (Gothenburg), The Royal Institute of Technology (Stockholm), Linköping Institute of Technology and Massachusetts Institute of Technology (Boston). This cooperation is directly enabled by the support of the Wallenberg Foundation. The CDIO project aims at improved engineering education by making the Conception-Design- Implementation-Operation—CDIO—of systems and products the main context of engineering education.

**STUDENT'S DIFFICULTIES WITH  $Z_{12}$ ,  
THE CYCLIC GROUP OF ORDER 12**

Daniel Siebert  
Brigham Young University  
dsiebert@mathed.byu.edu

Steven R. Williams  
Brigham Young University  
williams@mathed.byu.edu

In many abstract algebra classes, the cyclic group  $Z_n$  is introduced as a straightforward example of a factor group. It is generally assumed that this example is quite accessible to students. Our own experience teaching abstract algebra led us to question this assumption. In this paper we discuss students' misconceptions about  $Z_{12}$  and how these misconceptions point to the important concepts underlying an understanding of factor groups.

The data we discuss is from a one-semester study of an undergraduate abstract algebra class. Data include students' written work, field notes, videotapes of class instruction, and six semi-structured interviews with each of six target students. Beginning with the interview data, we looked first for examples of tasks that were difficult for students. Comparing successful and unsuccessful approaches, we looked for differences in their underlying conceptions of factor groups. This helped us identify important underlying concepts that led to successful responses.

When trying to make sense of  $Z_{12}$  as a factor group, our students had to engage in three different constructions: the factor group as sets, the factor group as cosets, and the factor group as representative elements. When approached from a formal mathematical perspective, all three of these constructions were equivalent. However, from a psychological perspective, each of these constructions requires fundamentally different understandings. Furthermore, our claim is that for students to truly understand  $Z_{12}$  as a factor group, they need to build and coordinate all three constructions.

## STUDENTS' UNDERSTANDING OF DERIVATIVE AND FUNCTION IN DIFFERENTIAL EQUATIONS

Karen S. Whitehead  
Purdue University

Kevin Dost  
Purdue University Calumet

This research informs us about university students' understanding of the concepts of function and derivative. The analysis considers both theoretical and practical issues. Theoretically, we add to an understanding of how students progress in understanding rate of change (Rasmussen, in press). Pragmatically, baseline information on students' understanding of function and derivative inform instructional decisions and curriculum design for a classroom teaching experiment in differential equations.

### Methodology

Individual interviews were conducted with eight students as part of a classroom teaching experiment in differential equations (Cobb, 2000). These eight students were chosen from a class of 30 on the basis of their willingness and the diversity of their answers in an intake survey that was administered the first day of class. There were two parts to the semistructured interview. First, we sought clarification and elaboration of the responses on the intake survey. Second, students worked through two tasks meant to reveal information about their conceptual understanding of rate of change and rate of change equations. These interviews were videotaped and transcribed; thus the data consists of the videotapes, transcriptions of the discussions, and copies of written work done by the students during the interview. To analyze our data, we reviewed it several times together, looking for patterns and trends in their verbal responses and written work.

### Discussion

Our analysis revealed two principal findings with respect to the students understanding of function. First, the students' concept image of function (Tall & Vinner, 1981) revolves around knowing function in a static sense. By this we suggest that students conceptualized function as a completed unchanging graph with one output for each input value. For example, when asked to define function, one student states "its a continuous line, increasing or decreasing  $\hat{A}$ ...each x-value can only have one y-value." Second, university students often maintain a more instrumental understanding of function as opposed to a relational understanding (Skemp, 1978). When asked why a graph is a function, the majority of students asked mentioned the vertical line test, a rule taught in algebra to determine functionality. When asked to elaborate, these same students were often unable to explain its basis, or mention more than a memorized answer.

Regarding students' understanding of derivative, the interviewees showed that they had a non-dynamic perception of rate of change. They have internalized the con-

cept of derivative as the slope of a tangent line, but do not see it as a changing quantity. For example, when given the differential equation  $dT/dt=0.3(T-70)$ , students replaced  $T$  with the initial value and drew an entire line with that same slope. This seems to confirm our hypothesis of how students' understanding of rate of change develops and suggests that in differential equations, students may learn to conceptualize derivative in more dynamic ways.

These results have ramifications for our work in the development of a differential equation course where concepts are primary and conceptual understandings imperative. These findings develop at both an individual and classroom level and what we learn will impact both arenas.

# **Algebraic Thinking**

## CONSIDERING THE ROLE OF COMPOSITE UNITS IN REIFYING EQUIVALENT EXPRESSIONS

Rose Dubec  
Purdue University Calumet  
rdubec@calumet.purdue.edu

Diana Underwood-Gregg  
Purdue University Calumet  
diana@calumet.purdue.edu

When solving equations of the form  $ax + b = cx + d$ , students struggle with the ontological essence of the expressions which form the equation. They may or may not have made the conceptual leap from an operational to a structural mode of thought. The authors site research and argue that part of the process of understanding students dilemmas involves observing students difficulties with composite units that are made up of both unknown and known quantities. These observations lay the groundwork for the further study of students' reification of algebraic expressions.

### Purpose

Several studies have noted the ease with which students are able to solve linear equations of the form  $ax + b = c$ . (see English & Sharry, 1996, Kieran, 1992, Fillory & Rojano, 1989, Sfard & Linchevski, 1994). In equations of this form, there is a clear distinction between the calculational processes,  $ax + b$ , and the result of the process,  $c$ . To solve tasks of this type procedurally, it is not necessary for the learner to have reified the expression  $ax + b$  as a quantity.

These same studies have also illustrated the difficulty students have in solving equations of the form  $ax + b = cx + d$ . To provide a theoretical grounding for understanding the reasons that underlie this difficulty, Sfard and Linchevski cast this inconsistency as the difference between students having an *operational* rather than a *structural* conception of an equation. In this paper, we use the term structural thinking to indicate that the learner has moved from viewing  $ax + b$  as only a calculational process to include viewing the expression as a mathematical object. When confronted with a situation such as  $3x + 24 = 2x + 70$ , the structural thinker will move beyond treating the right side of the equation as the "answer" to the left side of the equation. The learner who has made the conceptual leap to structural thinking must be adept at treating both sides of the equation operationally and structurally, as both computations and as mathematical objects. In addition, the equality sign must signify equivalence for the learner and a perfect balance of the quantities.

The purpose of our research is to assert that even when students can successfully solve such tasks when presented symbolically, they may have, at best, what Sfard called a pseudo-structural conception of algebraic expressions. In other words, if a student is able to correctly solve the task  $3x + 24 = 2x + 70$ , they may or may not be thinking about the equation structurally. Some students successfully act upon the expressions in appropriate ways because they are closely following a predetermined set of rules. We endeavored to construct a scenario in which students could demon-

strate the duality of their thinking. We argue that students' difficulties in doing so are closely related to their inability to perceive expressions of the form  $ax + b$  as *composite units* consisting of both a known and an unknown quantity.

We use the term composite unit in the sense developed by Steffe (1992). According to Steffe, when a child has developed a notion of composite unit, she can coordinate units of different rank. For example, she can treat a number, such as 23, as a single unit comprised of 23 ones, or as a group of 23 individual units and can move back and forth between these conceptions and coordinate them in flexible ways. She can think of a group of 23 combined with a group of 25 more as two groups of 20 and 8 more, or possibly think of them as 2 fewer than two groups of 25. This is the type of flexibility that is needed to have an understanding of place value numeration. In an analogous way, conceptualizing an unknown as a composite makes it possible to think of  $X+X$  as  $2X$  where  $2X$  is the result of counting  $X$  units, followed by counting  $X$  units again. That is, 1, 2, 3, ...,  $X$ ,  $X+1$ ,  $X+2$ , ...,  $X+X$ , where  $X+X$  is now seen as  $2X$ . In the same way, an algebraic expression such as  $3X-2$  can, depending on one's current needs, be viewed as a single composite unit, as  $3X-2$  individual units, as 2 fewer than 3 units of (size)  $X$ , or as 2 units of (size)  $X$  and 2 fewer than another unit of (size)  $X$ . In this way, this conceptualization of algebraic expressions is analogous to conceptions of place value numeration.

### Research Questions

The following research questions guide our investigation:

- How do students approach problem situations of the form  $ax + b = cx + d$  when these problems are not represented using conventional symbolism?
- Are students acting upon algebraic equations operationally or structurally?
- Have students reified both the unknown  $x$  as a quantity and expressions such as  $ax + b$  as a quantity?
- Do students comprehend that the equivalence of two expressions is maintained when equal amounts are removed from each expression?
- When unknown quantities are composed of both known and unknown amounts, can students break apart that composite unit into convenient pieces?

### Data Sources and Methods of Inquiry

The students who participated in this study were enrolled in a developmental-level beginning algebra course for university students. All of the students enrolled had completed high school algebra at some point in their schooling. An inquiry approach to mathematics instruction was employed, and instructional materials were developed as part of a classroom teaching experiment. We conducted pre- and post-semester

cognitive interviews with 11 students. The students' responses on tasks related to our research questions were analyzed using qualitative research methods. The interviews of two students (one who completed the course at the top of the class and one who struggled unsuccessfully) are highlighted in this study because they best represent the range of difficulties that students face.

Because the students had previously completed high school algebra we assumed that many would be familiar with algebraic equations of the form  $ax + b = cx + d$  and might be able to solve tasks using methods that they had learned in high school. To ascertain if these students would perform in a less ritualistic manner when the problem was presented within a context, we posed tasks such as the two described below.

Question #1. Cindy and Bobby have envelopes containing the *same amount* of money in all of the envelopes. Cindy has three envelopes and 24¢. (Actual envelopes containing money were placed in front of the students, as well as the "extra" change.) Bobby has two envelopes and 70¢. If Cindy opens all of her envelopes and counts her money, and Bobby opens all of his envelopes and count his money, they both have the same total amount of money. Can you use this information to help you figure out how much money is in each of the envelopes?

Figure 1.

Question #2. Cindy and Bobby have envelopes containing the same amount of money in all of the envelopes. Cindy has three envelopes and 80¢. Bobby has four envelopes and 24¢. If Cindy opens all of her envelopes and counts her money, and Bobby opens all of his envelopes and count his money, they both have the same total amount of money. Can you use this information to help you figure out how much money is in each of the envelopes?

## Results and Discussion

### Holly's Dilemma

Holly finished the semester as one of the top students in the class. She had done very well in high school, graduating in the top 4% of her class. When asked question #1, Holly quickly began writing  $3x + 24 = 2x + 70$ . She solved this equation procedurally by subtracting  $2x$  from each side and then subtracting 24 from each side and finished with  $x = 46$ . When asked if there was a way to confirm her answer, Holly wrote  $3(46) + 24 = 2(46) + 70$ , and said that “[We] just substitute it in and it should *equal*.” While it was clear that Holly was able to represent the task symbolically and solve it procedurally, we wanted evidence that she had truly reified  $x$ , that is, the unknown amount in the envelope as a static quantity and understood that the  $x = 46$  meant that there was 46¢ in each of the envelopes. We also looked for evidence that she had developed structural knowledge of the unknown quantities  $3x + 46$  and  $2x + 70$  in addition to her procedural knowledge of those quantities.

(The interviewer took away one envelope from each ‘child’)

Int: Who has more now?

Holly: Cindy has more. I think Cindy does. I have to figure it out. (Holly proceeded to write two new expressions,  $2x + 24$  and  $x + 70$ , to represent the new situation. Next, she substituted 46 for the unknown  $x$  into each expression and proceeded to evaluate each.) Oh, they have the same amount. Oh, look at that. I wouldn’t have guessed that!

The interviewer then removed another envelope from each collection, leaving Cindy with one envelope and 24¢ and Bobby with 70¢. Once again she asked Holly, “Who has more money?” Holly substituted 46 for the unknown  $x$  in  $x + 24$  and declared that each child had the same amount. When the interviewer asked Holly to explain why this occurred, Holly appeared to contemplate this question for several seconds before exclaiming, “Well Duh!, Because there’s 46¢ in each of those and if you take away that *equal* amount there will obviously be an equal amount left over.”

Those who have already reified algebraic expressions and equations may find it difficult to understand the crux of Holly’s dilemma. If she knew that there was 46¢ in each envelope, and that Cindy and Bobby had the same amount of money to start, how could she not understand that the equality of Cindy and Bobby’s amounts was maintained when one envelope (i.e., 46¢) was taken from each one? To understand the complexity involved in shifting one’s thinking from an operational approach to a structural approach, one must consider all of the following:

1. The unknown static quantity  $x$ .
2. The unknown total quantity of money that each child had was composed of known quantities (the change) and unknown quantities (the envelopes)

3. The unknown quantities of money  $ax+b$  and  $cx+d$  are each static quantities themselves in this situation and not just a series of operations on an unknown quantity.
4. The same quantity can be represented in different ways even when they do not appear on the surface to represent the same thing.
5. The issue of conservation of equality. That is, if we remove the same amount from both expressions, each quantity has changed, but the equality between the two new quantities is preserved.

Holly appeared to have reified  $x$  as a static quantity in this situation. However, one must consider that there are *two additional* unknown quantities *and* an equality to be considered in tasks such as these. The quantity in the envelope was unknown to the students, and the quantity of money that Cindy and Bobby had in all was also an unknown, but equal to each other, quantity. The envelope quantity could be represented by  $x$ . The unknown quantity that Cindy and Bobby had was composed of an unknown quantity,  $x$ , and a known quantity, the change, and is represented in two different ways,  $3x + 46$  and  $2x + 70$ . In these expressions, we have the same composite unit, the total unknown quantity, broken into pieces that do not immediately look like they represent the same amount. So when Holly had difficulty answering our questions, we needed to search for evidence of a reified  $x$ , a reified  $3x + 24$  and  $2x + 70$  as quantities, and a reified '=' sign.

### Pat's Dilemma

Pat was a middle-aged returning student. She struggled to make sense of most of the topics that she encountered over the semester. Pat was given question #1 and asked to figure out how much money was in the envelopes. Pat began by notating the task as shown below:

Figure 2.

Pat indicated that she understood that both Cindy and Bobby have the same amount of money, and yet insisted that "We have to somehow make them *even*." She then stated that she was unable to complete the task because she had forgotten the procedure for solving problems of this type.

The interviewer continued by taking one envelope away from both Cindy and Bobby and asked Pat who had more money now. Pat replied that, "We don't really know who has more money *now*." She was convinced that the interviewer had taken more money away from Bobby because "there was more money in each of his two envelopes than there was in each of Cindy's three envelopes." She indicated that this information would not help her in deciding who had more money. Pat was asked question #2, and she solved it in the same way. She was convinced again that by removing one envelope from each child, more money was being taken away from Cindy because Cindy had fewer envelopes.

The interviewer began the first task by reiterating that there was the same amount of money in each of the envelopes, and Pat shook her head in agreement and said, "okay." But Pat was unable to comprehend this idea. The money in the envelopes was not a static amount upon which she could act. She had not reified the unknown amount,  $x$ , as a static quantity.

Pat ignored the extra coins on the table in both tasks. She seemed unable to coordinate a quantity composed of a known and an unknown amount. Ignoring the 24¢ and the 70¢ allowed her to see the total amount of money that Cindy and Bobby had as a composite unit made up of only the envelopes. She then deduced that if the total amount in the envelopes, three for Cindy and two for Bobby, have the same value, then Cindy's envelopes must have less money in them than Bobby's envelopes. When the interviewer took one envelope away from each person, Pat said that more money was taken away from Bobby because the total amount divided by two meant more money in each envelope than the total amount divided by three for Cindy. Pat has not yet reified  $x$  as a quantity, nor  $2x + 24$  as a quantity, but she has reified the *unit*. For Pat, the unit was the total amount of money in the envelopes. She was able to decompose that unit into Cindy's  $1/2$  unit +  $1/2$  unit and Bobby's  $1/3$  unit +  $1/3$  unit +  $1/3$  unit, and she knows that the envelopes with  $1/2$  unit must have more money in them than the envelopes with  $1/3$  unit in them.

### Future Research

Holly was able to take the task and symbolically represent it using literal symbols. She displayed evidence of the reification of  $x$  because it was an object on which she operated. She knew that  $x = 46$  meant that there was 46¢ in each of the envelopes. It wasn't until the interviewer broke apart the  $3x + 24$  into  $2x + x + 24$  and the  $2x + 70$  into  $x + x + 70$  that Heidi lost her grasp of the situation.

At that point, were those  $x$ 's no longer the same quantity, the  $3x + 24$  no longer the same quantity as  $2x + x + 24$ , or was  $3x + 24$  no longer equal to  $2x + 70$ ? We can't make a definitive judgment about Holly's thinking. If we had taken only one side of the equation, say  $3x + 24$ , and asked Holly how that quantity would change if we removed one envelope, would she have been able to say that it would decrease by 46¢? If we had done that, it would have given us a clue as to the point at which her understand-

ing fell apart. Asking that question would have provided us with information about Holly's reification of  $3x + 24$ . I believe that if we had established that Holly had not yet reified  $3x + 24$ , we could conclude that she would be incapable of the reification of the equality  $3x + 24 = 2x + 70$ . The reification of the individual parts is necessary before a reification of the equality is possible.

It is interesting to note what Holly said after she procedurally figured out that the total amounts remained equal after one envelope was removed from each. She said, "I wouldn't have guessed *that!*" We wish we had asked her *why* she wouldn't have guessed that.

In our discussion, we will further elaborate on the complexity involved in developing a structural conception of algebraic equations and expressions. In addition, we will explain how the construct of composite units might be used as a potential pathway for designing instruction that would facilitate students' movement toward viewing algebraic expressions as both a process and an object.

# ON STUDENTS' FORMULATION OF SIMPLE ALGEBRAIC WORD PROBLEMS: SYNTACTIC TRANSLATION AND REVERSAL ERRORS AMONG TURKISH STUDENTS

Ayhan Kursat Erbas  
University of Georgia  
aerbas@coe.uga.edu

Yasar Ersoy  
Middle East Technical University  
yersoy@metu.edu.tr

The purpose of the study was to investigate how a group of Turkish high school students formulate algebraic equations from word problems. The study was designed as a replication of MacGregor and Stacey's study (1993), which provided evidence that students do not necessarily use syntactic translation, which is commonly cited as the main source of students' errors and difficulties in translating from natural language to algebraic syntax. We aimed to investigate students' errors and observe whether or not syntactic translation is dominantly used in the context of Turkish schools. We found that students generally use syntactic translation while forming equations from verbal statements, and that reversal errors are the most persistent errors in forming equations.

Many students have difficulty formulating linear algebraic equations from information presented in words (Clement, 1982; Clement, Lochhead & Monk, 1981; MacGregor & Stacey, 1993, 1997a, 1997b; Rosnick, 1981). *Syntactic translation*, in which translation of a statement in English into an equation occurs by replacing key words by mathematical symbols sequentially from left to right, is accepted as a procedure frequently used by students for formulating equations from natural language expressions, and is thought to be an important cause of errors, particularly the *reversal error* (Clement, Lochhead, & Monk, 1981). Although syntactic translation was the first source blamed for reversed equations, Clement et al. (1981) observed that another approach to writing equations was used frequently. In this approach, which they called *static comparison* and Herscovics (1989) called it *semantic translation*, the equation is used to represent an association of related groups, rather than equal numbers. On the other hand, MacGregor and Stacey (1993) reported that the majority of secondary school students did not use a syntactic translation procedure for writing simple linear algebraic equations; instead they tried to express the meaning of the statement and wrote incorrect equations. MacGregor and Stacey suggested that the majority of the incorrect equations, particularly the reversal equations, are consequences of cognitive models attempting to represent compared unequal quantities. In a different cultural context, Mestre (1989) reported that many Hispanic students have misconceptions in solving the Student-Professor problem (Clement, 1982) such as " $6S = 6P$  and  $6S + P = T$ ," which are originated in language differences. He concluded that differences in language cause Hispanics to commit the same types of errors as Anglos, but with a higher frequency. Therefore, we can hypothesize that types of errors in word problem translation are similar in different contexts and linguistic differences do not seem to

qualify as a major source of errors. As a part of a larger research concerning teaching and learning of elementary algebra in Turkish schools (see Erbas, 1999; Ersoy & Erbas, 2000), we investigated how a group of Turkish high school students formulate algebraic equations from word problems. In particular, we were interested in whether Turkish students used syntactic translation and performed reversal errors as frequently as reported in the research literature.

### Method

We selected 217 ninth-grade students from 4 high schools, two public academic (PuAc), one private (PrSc), and one vocational-technical high school (VoTe) in a socio-economically middle-class district of Ankara, Turkey using "simple random sampling method" (Fraenkel & Wallen, 1996). Two classes from each school (eight in all) were chosen based on availability and permission of participant schools. Students' frequencies and percentages according to their gender and schools can be seen in Table 1.

**Table 1.** Distribution of Students According to Their Schools and Gender

| Schools  | Female    |           | Male       |           | Total<br><i>n (%)</i> |
|--|-----------|-----------|------------|-----------|-----------------------|
|  | <i>n</i>  | <i>%</i>  | <i>n</i>   | <i>%</i>  |                       |
| <i>PrSc</i> : Private School                   | 15        | 43        | 20         | 57        | 35 (16)               |
| <i>VoTe</i> : Vocational-technical High School | 6         | 12        | 44         | 88        | 50 (23)               |
| <i>PuAc-1</i> : Public Academic-1              | 36        | 49        | 37         | 51        | 73 (34)               |
| <i>PuAc-2</i> : Public Academic-2              | 23        | 39        | 36         | 61        | 59 (27)               |
| <b>Total</b>                                   | <b>80</b> | <b>37</b> | <b>137</b> | <b>63</b> | <b>217 (100)</b>      |

We administered a simple paper-and-pencil test consisting of five items, four of which were open-ended (classical) and one was multiple-choice. All of the five items used can be seen in the Appendix. Four open-ended items (A, B, C and E) required students to formulate a simple linear equation from information given in words. The multiple-choice item (D) required students to identify the correct equation from a set of alternatives. Four items were translated replicas that MacGregor and Stacey (1993) used. Instead of the fifth item used by MacGregor and Stacey, we decided to use "The Students and Professors Problem" (Clement, 1982). In rewriting the items in Turkish format, we tried to preserve the essential characteristics of the items including the order of algebraic symbols/letters/variables and the numerals, sentence structure, and the meaning. However, the difference between the grammatical structure of a sentence in English and Turkish made preserving the location of keywords (i.e., verbs such as equal, be; comparatives such as more than, less than, etc.) difficult if not impossible. For example, in item A, although the order and structure of key words is *z*, "is equal to", "sum of", 3, *y* in English (MacGregor and Stacey, 1993), it is *z*, 3, *y*, "sum", "is equal to" in the Turkish translation. Readers may compare the keyword orders of

the items from the tables we provided below. In the analysis of the answers, we took the differences between two languages into consideration and made the comparisons accordingly.

After we prepared the mathematics teachers, they administered the test to their own students in the fall semester of the 1998-99 academic year. The students had no time restrictions. In the data analysis and presentation, we followed the same pattern described in MacGregor and Stacey (1993). The alpha reliability of the test (Cronbach, 1951) was calculated as 0.73.

### Results

The percentages of students correctly answering each item can be seen in Table 2 and Table 3. Except for the Item A, all items were more difficult than had been expected, with success rates ranging from 40% on item D to 83% for Item A. Because of high omit rates, the percentages of success rates for the whole sample was even smaller.

**Table 2.** Percentages of Correct and Incorrect Responses for the Students Answering the Items

| Item* | n   | Correct (%) | Incorrect (%) |
|-------|-----|-------------|---------------|
| A     | 121 | 83          | 17            |
| B     | 122 | 60          | 40            |
| C     | 109 | 49          | 51            |
| D     | 150 | 40          | 60            |
| E     | 90  | 62          | 38            |

n shows the number of students answering the items

\* See Appendix for Items

To investigate the use of syntactic translation, like MacGregor and Stacey (1993) we followed the strategy of classifying students' responses as "possibly syntactic" and "definitely not syntactic" (p. 224). In that process, the key idea was that if the students mainly use syntactic translation then they would use the symbols, numerals, and variables in the same order that they appeared in the wording of the question. For example, in item A, if students used a syntactic translation then they would construct the equation as " $z = 3 + y$ " perceiving "is equal to" as an indicator of equality sign and keeping the order of variables. Like MacGregor and Stacey, we allowed some "cosmetic changes" (p. 224) in the position of numerals when deciding if a response indicated word-order matching. As MacGregor and Stacey pointed out

**Table 3.** Percentages of Correct, Incorrect, and Omitted Responses for All of the Students

| Item* | N   | Correct (%) | Incorrect (%) | Omit (%) |
|-------|-----|-------------|---------------|----------|
| A     | 217 | 46          | 10            | 44       |
| B     | 217 | 34          | 23            | 44       |
| C     | 217 | 24          | 26            | 50       |
| D     | 217 | 28          | 42            | 31       |
| E     | 217 | 26          | 16            | 59       |

N shows the whole number of students taking the test

\* See Appendix for Items

...many students are thought that  $3 + y$  is normally written as  $y + 3$  and  $y \times 8$  is normally written as  $8 \times y$  or  $8y$ . Therefore, it was considered that the responses  $z = y + 3$  for Item A and  $s = t + 8$  for Item C could have been produced by the syntactic method. For Item B, a student might use syntactic translation to get the sequence  $y.8 = z$  and then move the "8" to give  $8y = z$ . We have allowed this and similar expressions as an evidence of possibly syntactic translation. Furthermore, allowance was made for incorrect translation of the operation. For example,  $y + z8$ ,  $y + 8 = z$  were judged as indicating syntactic translation of Item B. By allowing for cosmetic changes and mis-translation of the operation, we hoped to identify every response that could have resulted from an initial syntactic translation. (p. 224)

The numbers of responses classified as "possibly syntactic," "definitely not syntactic," and "unclassified" are shown in Table 4a and Table 4b. The corresponding percentages of attempted responses for each item are shown in Table 5. As MacGregor and Stacey did, we classified responses as definitely not syntactic if the first variable in the item was used as the second variable or an inverse operation was used in the response. However, there were several responses that we could not classified either as "possibly syntactic" or "definitely not syntactic." For example, summing every numeral and letter used in the item (i.e.,  $s + 8 + t$  in Item C). We classified those as "unclassified."

Contrary to MacGregor and Stacey, we observed, overall, that classifiable responses were likely to match word order. Only the data for Item E in Table 5 and Table 6 provide no support for the proposal that syntactic translation was a procedure commonly followed by the students in the sample. However, in total, the data in Table 5 and Table 6 provide support for the proposal that syntactic translation was a procedure commonly followed by the students in the sample. As shown in Table 5, more than half of the correct responses were syntactic. This does not look surprising because syntactic translation seemed so easy for the items. However, we cannot

Table 4a. Students' Responses to Items A and B

| $s+8=t$  | 20        | $t=s-8$  | 1         | $8s=t$  | 2         |
| $s.8=t$  | 1         | $t=s+8$  | 10        | $s=t8$  | 2         |
| $8+s=t$  | 3         | $t=8+s$  | 2         |         |           |
| $8s+t$   | 2         | Other    | 6         |         |           |
| $s+8t$   | 5         |          |           |         |           |
| $s=8t$   | 1         |          |           |         |           |
| $s+t=8$  | 1         |          |           |         |           |
| Item E (6, "times as many", "Students", "Professors") - Key word order in English      |           |          |           |         |           |
| ("Professors", 6, "times as many", "Students") - Key word order in Turkish translation |           |          |           |         |           |
| $P=6S$   | 6         | $S=6P$   | 29        | $S.P$   | 2         |
| $6P=S$   | 14        | $6S=P$   | 9         |         |           |
| $P6=S$   | 5         | $6(S+P)$ | 2         |         |           |
| $P6S$  | 1         | $S6=P$   | 2         |         |           |
|  |           | $S/6=P$  | 1         |         |           |
|  |           | $S=P6$   | 9         |         |           |
|  |           | $S=P$    | 2         |         |           |
|  |           | $SP=6$   | 1         |         |           |

say that syntactic translation produces a greater error rate than those of non-syntactic translation. Contrary to MacGregor and Stacey, Table 5 and 6 do not provide strong evidence to reject the hypothesis that the words "*is equal to*" (p. 226) prompt syntactic translation. As may be seen in Table 5, many more students gave possibly syntactic responses for Item A than for the others and the number of incorrect responses is less than that of the non-syntactic.

**Table 5.** Frequencies of *Possibly Syntactic*, *Definitely Non-syntactic*, and *Unclassified* Responses to Items A, B, C, and E

| Item  | n   | Possibly Syntactic |           | Not Syntactic |           | Unclassified |           | No Attempt |
|-------|-----|--------------------|-----------|---------------|-----------|--------------|-----------|------------|
|       |     | Correct            | Incorrect | Correct       | Incorrect | Correct      | Incorrect |            |
| A     | 121 | 82                 | 8         | 19            | 8         | 0            | 4         | 97         |
| B     | 122 | 69                 | 13        | 5             | 33        | 0            | 5         | 93         |
| C     | 109 | 40                 | 33        | 12            | 18        | 0            | 6         | 110        |
| E     | 90  | 19                 | 7         | 38            | 24        | 0            | 2         | 129        |
| Total | 442 | 210                | 61        | 74            | 83        | 0            | 17        | 429        |

n: The number of students answering the items

**Table 6.** *Possibly Syntactic* and *Definitely Non-syntactic* Responses as % of Total Responses to Items A, B, C, and E

| Item  | N   | Possibly Syntactic | Not Syntactic | Unclassified |
|-------|-----|--------------------|---------------|--------------|
| A     | 121 | 90 (74%)           | 27 (22%)      | 4 (3%)       |
| B     | 122 | 82 (67%)           | 38 (31%)      | 5 (4%)       |
| C     | 109 | 73 (67%)           | 30 (28%)      | 6 (6%)       |
| E     | 90  | 26 (29%)           | 62 (69%)      | 2 (2%)       |
| Total | 442 | 271 (61%)          | 157 (36%)     | 17 (4%)      |

n: The number of students answering the items

We observed that, for all items, most of the errors were reversal. Table 7 shows the number of reversed responses for items A, B, C, and E and the percentages within the total and incorrect responses.

In total, 68% of the incorrect results are reversal errors. This seems surprising since the test items (except the Item E: The S-P problem) were designed (by MacGregor and Stacey) to reduce or overcome those previously published causes of reversal. The percentages of reversal in total responses were lower than those in MacGregor and Stacey. Furthermore, the percentage of reversals in Item E was greater than for the other items. This might be attributed to the fact that it was not constructed to eliminate all previously published causes of reversal. This observation might also be thought of as the structure of the Items A, B, C being effective in reducing reversal errors.

Table 7. Reversal Errors in Responses to Items A, B, C, and E

| Item  | Total Responses | Reversed Responses |                      |                          |
|-------|-----------------|--------------------|----------------------|--------------------------|
|       |                 | Frequency          | % of total responses | % of incorrect responses |
| A     | 121             | 9                  | 7                    | 45                       |
| B     | 122             | 34                 | 28                   | 67                       |
| C     | 109             | 40                 | 37                   | 68                       |
| E     | 90              | 26                 | 29                   | 79                       |
| Total | 442             | 109                | 25                   | 68                       |

In most curricula and classroom practices, students are often experienced in solving equations, but not necessarily experienced in constructing or writing equations. This point lead us to consider that in a multiple choice item/test environment students might do better than open response format. Item D, constructed as a multiple-choice item, was included for this reason, as did MacGregor and Stacey. As seen in Table 8, contrary to expectations, only one-third of the students in total were successful in identifying the correct equation from among the choices. A comparison of schools shows a success rate ranging from 16% to 57%. Considering that the fourth and fifth alternatives ( $6x = y$  and  $6 + x = y$ ), definitely, included reversal errors, about one-third of all the students chose reversed equations. This situation is parallel to the other items.

Table 8. Students' Correct and Incorrect Choices for Item D

| Schools | N   | Correct     |    | Incorrect |   |             |   |          |    |             |    | Omit |    |
|---------|-----|-------------|----|-----------|---|-------------|---|----------|----|-------------|----|------|----|
|         |     | $x = 6 + y$ |    | $x = 6y$  |   | $x = 6 - y$ |   | $6x = y$ |    | $6 + x = y$ |    |      |    |
|         |     | f           | %  | f         | % | f           | % | f        | %  | f           | %  | f    | %  |
| PrSc    | 35  | 20          | 57 | 0         | 0 | 1           | 3 | 2        | 6  | 7           | 20 | 5    | 14 |

| Total   | 217 | 62          | 29 | 4         | 2 | 8           | 4 | 20       | 9  | 56          | 26 | 67   | 31 |

### Discussion and Conclusions

In contrast to MacGregor and Stacey (1993), our results do not cast serious doubt on syntactic translation as a major cause of errors in formulating equations. However, the reversal error has been shown to apply to a wider class of equations than was previously considered as pointed out by MacGregor and Stacey. Like MacGregor and Stacey, the present study has shown that the reversal error occurs not only in multiplicative items but also in additive items that relate to very familiar situations.

Furthermore, as MacGregor and Stacey (1993) have pointed out, the high percentages of reversal errors in Items B, C, D cannot be attributed to previously identified causes such as *static comparison of associated sets of objects, the use of algebraic letters as abbreviated names, the interpretation of numerals as adjectives, frame retrieval errors, and complex or misleading English syntax* (here Turkish). Although all these factors could have had an effect on the items previously reported in the literature, they were eliminated as much as possible from the items used in the present study. Moreover, we found that a high percentage of students committed reversal errors in Item E for which no such precautions were made in its adaptation into Turkish. The percentage of reversal errors in this item was higher than that in other items. Clearly, the precautions taken against previously identified causes were significantly effective to avoid the reversals. Since we cannot reject that students used syntactic translation, we cannot ignore the effect of it on reversal errors here. As we hypothesized at the beginning, types of errors in word problem translation are very much on a same line in different contexts and linguistic differences do not seem to qualify as a major source of errors. However, this claim needs to be verified with more research focused on language differences and their affect on algebraic problem statement, formulation and solution.

We conclude that without the change in cultural context, syntactic translation appears to be widely used among algebra students. We hypothesize that this is mainly the result of instructional practices and classic textbook emphasis that focuses on the procedures rather than meanings. Students often are taught to solve word problems by seeking the key words and word order matching techniques, which are key in syntactic translation.

As Herscovics (1989) proposed, students are taught the syntax of a language without the semantics. Namely, they know the rules in the grammar but they do not understand the words. As a result, students often develop what Skemp (1976) calls an “instrumental understanding” of algebra: “It is what I have in the past described as ‘rules without reasons,’ without realizing that for many pupils *and their teachers* the possession of such a rule, and the ability to use it, was what they meant by ‘understanding’” (p. 153). However, it is well recognized that to educate a generation for tomorrow’s world where demands will be placed on problem solving and communication skills, we need to shift instruction away from routine symbolic manipulation and procedures toward an in depth, “relational understanding” (Skemp, 1976) of algebra (Booth, 1989). Thus, students should be provided with meaningful tasks that develop critical thinking skills and enhance appreciation for the usefulness of algebra. As Davis (1989) cautioned, these mathematical tasks should be of a genuine nature, not the artificially contrived word problems found in many texts.

#### Note

\* The items A, B, C, and D were taken from MacGregor and Stacey (1993) and the item E was taken from Clement, Lochhead & Monk (1981).

vvcifare@email.uncc.edu

The project leverages students' fascination with 3D digital entertainment and medieval fantasy stories to teach mathematics, including beginning algebra, to middle school students by situating the mathematics in an appealing computer environment based on massively multi-player role-playing games (MMPRPG). The development team for *Warrick's Secrets* consists of individuals from the information technology (IT) industry and researchers from three universities. *Warrick's Secrets* is the result of a Phase I Small Business Innovation Research (SBIR) grant completed for the US Department of Education in April 2001 and Physitron, Inc. internal research and development funding. Second stage research and development continues following the September 2001 awarding of a Phase II SBIR by the U.S. Department of Education. Phase I and II versions of *Warrick's Secrets* are constructed as single-player role-playing games (RPG). The RPG is used to deliver National Council of Teachers of Mathematics (NCTM) *Standards*-based educational content. The system includes advanced 3D computer rendering capabilities and high quality 3D artwork since both have proven crucial to maintaining players' attention in the gaming community. The results of the Phase I prototype study are reported along with the progress of the Phase II program.

### **Background and Theoretical Framework**

#### **What are Massively Multi-Player Role Playing Games?**

*Warrick's Secrets* is modeled on currently popular MMPRPG's such as Ultima Online (UO), Everquest, and Asheron's Call. Currently, more than 150,000 customers play Electronic Arts Ultima Online-- including players from 114 countries (Walton, 2000). Sony's EverQuest and Microsoft's Asheron's Call each have a substantial customer base as well. A MMPRPG is a game with a thousand or more players gaming concurrently in real time in the same virtual world. Role-playing indicates that a human player controls an in-game character's speech and actions. The virtual world in the most successful games contains aspects of the historical middle ages, including some degree of fantastic creatures (e.g., dragons) and magic. Due to limited resources and time, Phase I and II prototypes of *Warrick's Secrets* only support single-player activity. With future funding, we will add multi-player capabilities. At first glance, some people mistakenly think the educational tool described and the total system planned differs little from existing products which attempt to make learning into a game. Our approach is to tightly integrate the educational content with a MMPRPG.

This seemingly subtle difference (integrating educational content with a particular game genre versus attempting to make learning into a game) has an enormous impact on the way students react to the tool. There are several differences in our approach that increase the student acceptance rate, potential learning success rate, and age range for which the teaching tool can successfully be used. Some of these advantages are listed below.

- *Warrick's Secrets* is a mathematics educational tool that is based on currently popular commercial MMPPRG concepts.
- *Warrick's Secrets* is based on NCTM *Standards* for middle school mathematics and provides teachers with a mapping of each mathematical challenge to the corresponding topic/skill within the standard.
- Educational content imbedded into realistic situational context.
- Inherent promotion of cooperative learning.
- Ability for students to interact with remote students (In Phase III).
- Vehicle for covert and overt learning.
- Advanced motivation and reward system.

### **Related Research**

Mathematics education research areas germane to this project include situated perspectives on learning and constructivist views of representation. Mathematics viewed as socially constructed knowledge has strongly influenced other learning theories. Many researchers (Kieren, 2000; Steffe & Thompson, 2000; Sfard, 1998; and Cobb & Yackel, 1996) describe the theoretical underpinnings of their work in terms of "social constructivism." The learning theory that grounds many of these researchers, including those in the present project, may be traced to von Glasersfeld's (1991) radical constructivism, and Piaget's (1970) genetic epistemology. Lave and Wenger (1991) describe situated learning as developing as a function of the activity, context, and culture in which it occurs. One of the primary benefits of integrating educational content with a virtual environment and storyline is that educational content can be imbedded into a realistic situational context. These ideas are important because we consider how such theories apply to the development of educational interactive multimedia. An example of such multimedia research is the work of Herrington and Oliver (1997).

Mathematical representation is considered from a constructivist perspective. Representation describes the form in which a problem is encountered—such as graphical, numerical, verbal, or symbolic representations. It also describes the learner's mental construct of the problem. One of the major advantages of the virtual environment for problem solving is that students have many opportunities to attempt solutions of mathematical tasks. The virtual environment affords a natural mechanism for provid-

ing hints and alternative teaching representations based on a student's previous success with a concept or skill. This may increase the number and quality of the mental representations that students apply to the problems. The project relied on the notion of reflective abstraction to explain how, as students work through multiple attempts to solve a problem, they may develop progressively more abstract mathematical conceptions. It has previously been observed (Cifarelli, 1988; Goodson-Espy, 1998) that if students cope with recurrent mathematical themes, they are more likely to develop higher levels of reflective abstraction, and thus attain more powerful mathematical concepts.

### **Research Questions**

The project examines several research questions, including the following:

- Does playing this type of game raise the performance level of students in a regular mathematics classroom?
- Can the notion of reflective abstraction be used to describe mathematical concept building in the MMRPG setting?
- Will our collection of situation-based and “scaffolded” mathematics pathways encourage students to apply problem-solving skills that encourage the development of higher order thinking?
- If allowed to create their own character, what kind of character do they choose in terms of gender, race, ethnicity, facial appearance, and clothing?
- Will this educational resource be popular with females?
- Do students display an increased motivation to try to solve problems? Do students with math anxiety behave differently when they assume a character within a virtual world to solve problems?
- Can standards-based mathematical content be integrated into an MMRPG in a manner that allows students to learn without forcing the student to step out of the role of their online character?

### ***Warrick's Secrets* Development Process**

#### **Game Play Design and Storyline**

The game world of *Warrick's Secrets* is set in what is often called the “fantasy” genre. The fantasy genre has historically proven considerably more successful than other alternatives (e.g., science fiction, western) across the total spectrum of games—table-top, single player computer, and multiplayer computer. The fantasy genre is akin to earth's historical “middle age” with the addition of magic and monsters. Given that it is a fictitious world, creating an engaging “back-story” to draw the player into the game world is a primary challenge. Our story traces the footsteps of a boy named

Palus as he travels from his home in the “Old Country” to attend a magical academy in the Northlands. Being sensitive to gender-issues in math education, Phase II and subsequent editions vary the name, sex, and ethnicity of the back-story protagonist. Although the central purpose of the back-story is to immerse the player into the game world, a variety of subtle features exist. First, the character is of an age to which players can relate. Second, and perhaps analogous to the experience of many underprivileged children in America, the character is an immigrant. Third, the character is portrayed as self-reliant and resourceful. Palus is both willing and able to undertake this journey on his own initiative. Fourth, while cautious, Palus is nevertheless friendly and hospitable to strangers in need. Fifth, the story includes several different races of peoples. From the back-story, players are introduced to the game world, a world where monsters and magic exist, in a crisp and effective manner. Another important consideration for an edutainment system is the integration of gameplay with content. A base requirement for any game system is that it pass the “fun test.” That is, is it enjoyable to play? As such, for this short prototype we were challenged to showcase not just a potential for math education delivery, but also a fun game within a concise timespan. In order to give students at least a taste of how fun the gameworld and game engine could be, we employed a wide range of user activities. For example, although the demo features a very small portion of the Warrick Academy, students playing as Palus do see multiple levels, diverse art and architecture, use stairs, and meaningfully interact with a variety of objects (e.g., potion flasks). The “first-person” style engine allows the players a tremendous sense of opportunity and control as they move through their environment. Although the students’ actions are being directed, good game design creates the persistent illusion that the character could “go anywhere” or “try anything.” The back-story is literally just the introduction to the larger issues of game content and gameplay.

### **Software Development**

The Phase I and II prototypes of *Warrick’s Secrets* were developed as “mods”, (modification) to the computer game, *Deus Ex*, that was developed using the popular *Unreal Tournament* game engine. The *Deus Ex* Editor and *Deus Ex* Conversation Editor were used extensively to create the prototype. The only avatar (player maneuverable character) for the Phase I prototype was Palus, a male student character. Additional avatars, to include females and characters of different ethnicity are being developed for Phase II. To achieve the same capabilities as commercial MMPRPG’s we plan in Phase III, to incorporate the ability for students to choose the following character attributes: gender, race, facial appearance, and clothing.

### **Problem Pathways and Hints**

A quest in *Warrick’s Secrets*, embedded within the storyline and directly involving the action of the characters, illustrates a mathematical concept or skill through a collection of problems, called a problem pathway. The more advanced structure for

our Phase II quests is illustrated in Figure 1. The path through a quest is structured based on the student's responses and includes a collection of scaffolded hints that are provided to the student, when necessary. The structure of our Phase II scaffolded hints is illustrated in Figure 2. In order to complete a quest, the student must navigate through the virtual world, interact with the conversation tools, mentor characters, and the objects involved in the quest. Because this is a fantasy environment, interacting with the objects involves conversations and active responses with the quest objects.

### **Example Quest and Problem from the Phase I Prototype**

The Phase I prototype included a basic quest. The collection of problems in the quest was directed at helping students develop or refine the skills necessary to solve problems involving mixtures. The student character, Palus, meets a magical mentor, Adel. The first challenges required him/her to solve a series of problems involving representations of percent. For example, in the introductory meeting between Palus and his mentor, Adel, Palus sees a projection of Adel's image in an entry hallway of the castle. Adel gives Palus instructions on how to navigate in the castle in order to find the room where Adel is waiting for him.

**Adel Projection:** It is one thing to talk about how understanding the nature of reality affords those with the 'gift' the ability to harness magical energies, and quite another to experience it. Let us consider a sample challenge, and you can demonstrate your knowledge.

**Adel Projection:** Imagine that I give you a collection box like the one projected onto the window of enlightenment behind me. An alchemist uses such a box to help gather and organize various alchemical components. I might, for example, ask you to put a fire moth wing into every bin. After an hour of capturing fire moths in the forest, perhaps your box would look like the projection behind me. What is the percentage of filled cells in the collection box?

If the student was not successful, he or she was provided with a series of hints and provided with opportunities to try again. The next series of challenges required Palus to interact with a series of talking flasks in the laboratory. The flasks helped Palus learn to read the measurements on a flask and, in a progressive manner, helped him/her gradually learn how to solve a mixture problem and learn how to represent it algebraically.

**Adel:** Welcome to the laboratory. Now that I see you in person, I have something for you. Take this wand lying before me. (After I've told you about it, right-click on it.) The wand's crystal can be treated with a potion to make it shine like a lit torch. The first formula for such a potion was developed long, long ago by a Darslang War-Wizard named Kazuhide. He used it with great

success to search inside deep caverns where gas and winds would extinguish an ordinary torch. It was for generations a closely guarded secret, handed down only to his descendants. But, these days it's a very common potion, and our students call the mixture "liquid stars".

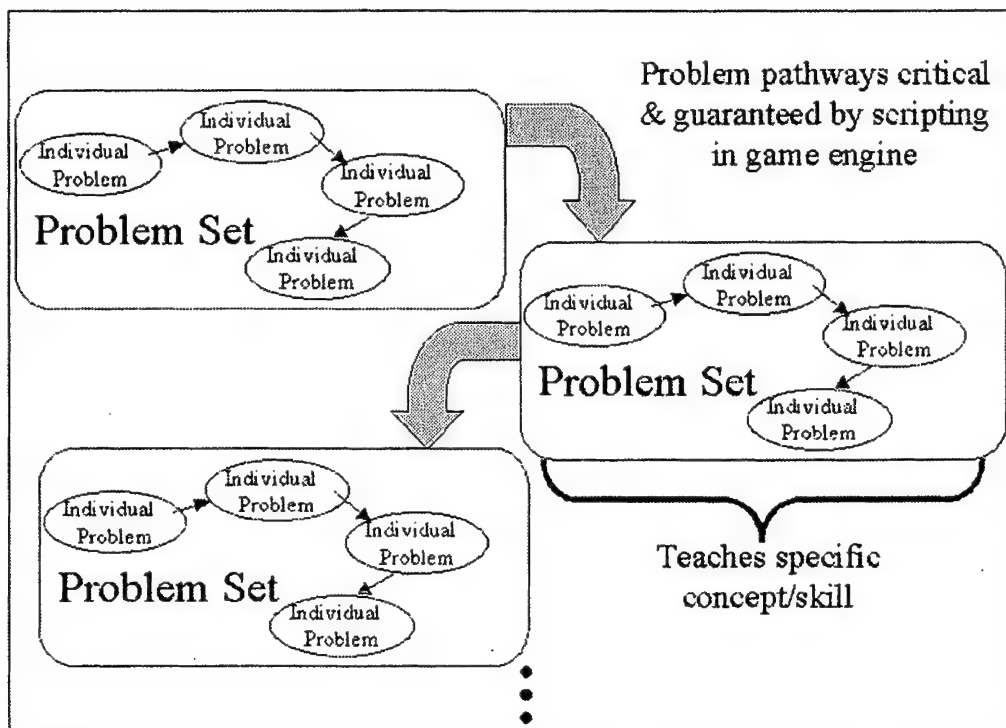

Figure 1.

**Adel:** To make the liquid stars potion, we start with a fire moth solution—what we alchemists call 'fire-water'. Earlier this morning I ground up a batch of fire moth wings to make some fire-water just for you to work with, Palus. I want you to learn how to make the 'liquid stars' potion, so you can use the wand to produce light when needed. Let us begin with the first flask on the bench. Oh, and these flasks are rather special. They will help you with your potion creation and review of mixtures. Each flask will assist you with your potion creation skills if you get near it, Palus. Now, approach the flask closest to this end of the bench, please. After you have picked up the wand, you should approach each flask in turn.

**Action Triggers Flask1:** Each fire-moth wing produces 1 mL of liquid fire-water. When I'm full I hold 100 mL. How much fire-water do I currently contain? (Visual representation of flask appears and a collection of multiple choice answers is offered.)

**Action:** *If Palus gets an incorrect answer, a hint is provided and he is allowed to try again.*

**Flask1:** Great. You are one fourth of the way done with the liquid stars potion. Let's consider the next step in making your potion. Fire-water can be used in many different potions, but often has to be diluted; so let's move on to the second flask.

**Action Triggers Flask 2:** I can hold 100 mL and contain fire-water diluted with flying fish oil. If the fire-water solution has a 50% concentration of flying fish oil, then tell me, Palus, how many mL of flying fish oil do I have? (Visual representation of flask appears and a collection of multiple choice answers is offered.)

**Action:** *If Palus gets an incorrect answer, hints are provided and he is allowed to try again.*

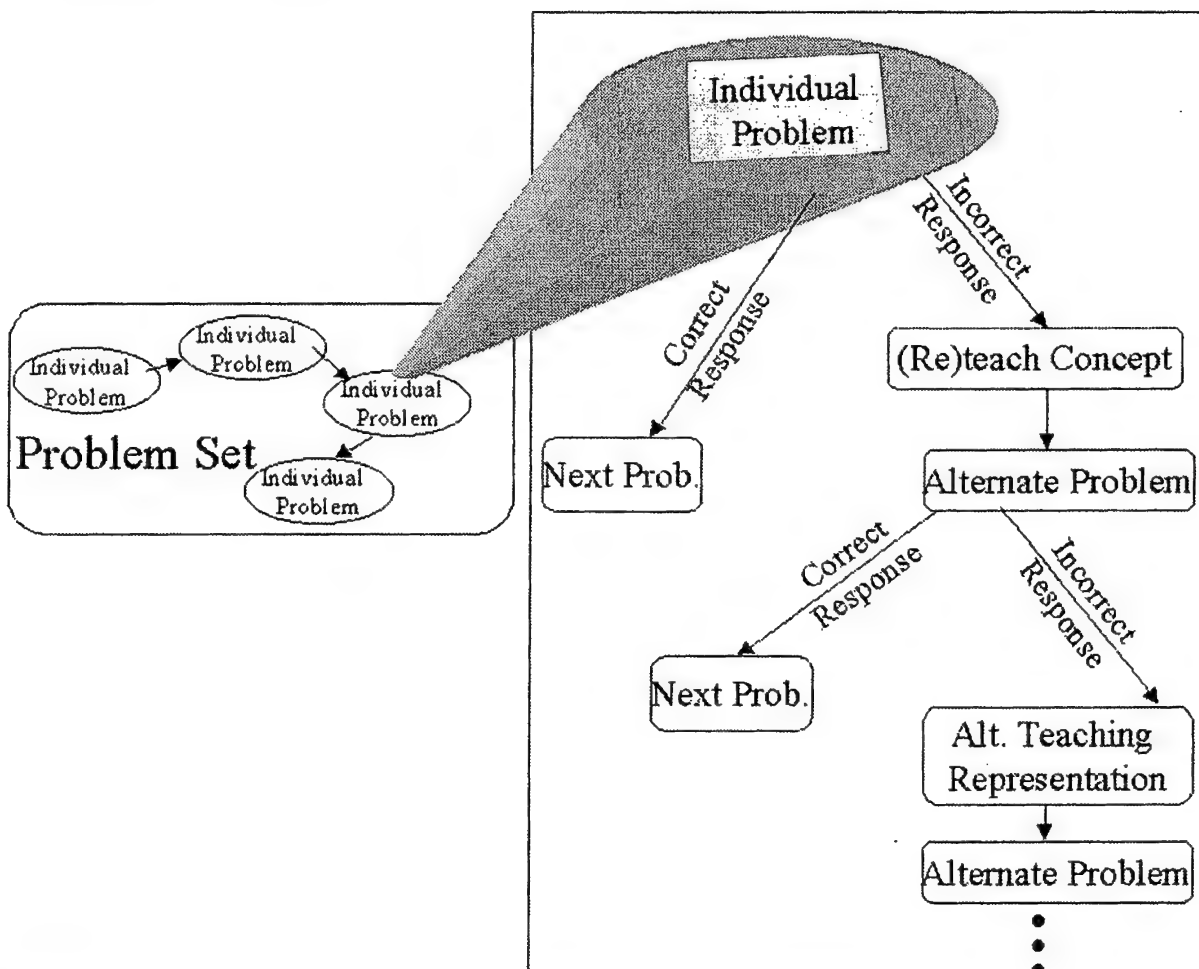

Figure 2.

BEST COPY AVAILABLE

**Flask2:** Excellent work, Palus. We diluted that 25 mL batch of fire-water with an amount of flying fish oil. Let's do the same thing, but in a slightly larger quantity with the third flask.

**Action Triggers Flask3:** Once again we have a fire-water solution that has been diluted to 50% concentration with flying fish oil. Notice how many total milliliters I contain, and tell me how much flying fish oil I contain. (Visual representation of flask appears and a collection of multiple choice answers is offered.)

**Action:** *If Palus gets an incorrect answer, hints are provided and he is allowed to try again.*

**Flask3:** That is wonderful, Palus. You are indeed a very promising pupil. And, we have now done three-fourths of the steps needed for your liquid stars potion. The mixture of fire-water and flying fish oil in even parts is sometimes called "hotfish soup" by the students in the lab. "Hotfish soup" is used in many different potions that produce heat or light, or even fire. Actually, the hotfish soup is still a bit too volatile for just making light, and needs further dilution. So, you should move to the last flask to complete the potion.

**Action Triggers Flask4:** I have 75 milliliters of liquid, which is hotfish soup diluted with the spittle of glowworms. If there is a 30% concentration of glowworm spittle, then how many milliliters of glowworm spittle do we have?"

Through the use of the backstory, students are provided with a rationale and motivation for completing the quest. As is customary in MMPRPGs, the successful completion of a task results in the player being rewarded with a desirable object or new character skill. The successful completion of Quest 1 results in Palus receiving a lighted wand that is necessary to navigate the underwater corridors required to complete the next quest. The prototype, including this series of challenges, was pilot tested with middle school students, as described below.

### Methods

#### Subjects

The subjects included seven students from a middle school in the southern US. These included two sixth graders, two seventh graders, two eighth graders, and one ninth grader. The subjects included one African-American, six Caucasians, four males, and three females.

#### Data Sources and Analysis Method

The game prototype testing took place at school on April 6, 2001. The individual sessions each lasted between 45-60 minutes. Students attempted all the problem sce-

narios developed in the game, completed a questionnaire and participated in a concluding interview. Students were given a pen, paper, and a calculator. The problem sets included two paths called “challenges.” The first “challenge” consists of a set of problems involving percents. The second “challenge” consists of a series of progressive problems involving concepts involved in mixture problems. The data sources for the analysis of the pilot study include: (1) videotapes of the prototype testing sessions, (2) student-written artifacts, (3) completed questionnaires, (4) observational field notes, and (5) researcher notes from the post-game interviews.

## Results

### Summary of Results

- *MMPRPG Environment.* All subjects expressed increased interest in working on mathematics problems that were situated in a computer gaming environment. Students explained that the game made learning math easier for them because it placed the mathematics into a meaningful context for them. Students indicated that they were motivated to solve problems because they wanted to find out what would happen next in the game or because they wanted to gain access to the next magical tool that was described in the story.
- *Tool Use and Concept Development.* The structure of the game and the quests actively encourage tool use in representing problems. Students indicated that they were motivated to persist in problem-solving due to the constant availability of tools, such as the in-game help system. These may be viewed as self-generated representation tools that may have a bridging effect, providing opportunities for students to build on their current conceptions by suggesting seeds of ideas that the students may not have thought of, but may prove useful for exploration in order to solve the problem.
- *Expressions of Student Confidence.* In surveys, problem-solving sessions, and post-session interviews, subjects reported confidence in solving mathematics problems in the game setting but expressed less self-confidence in terms of solving word problems in a classic classroom or textbook setting. All of the students attempted all of the problem scenarios. Two of the subjects were able to solve all of the problems on the first try. Three of the subjects were able to solve all but one of the problems on the first attempt. Because of the visual representations of the problems and the scaffolded hints that could be accessed, students were willing to attempt what they considered to be difficult problems.
- *Role of Graphics.* High quality graphics, in conjunction with an interesting back-story for the game, kept students interested in the game and in working on the challenges. The students indicated that they found the collection bin representations for the initial percent problems to be very helpful in solving these problems.

The students were emphatic that the visual representations were extremely useful to them. The students' interactions with the flasks in the laboratory appear to have influenced their problem-solving success with the mixture-related problems. Students indicated that it was easier to solve the problems because the in-game flasks were displayed with measurement calibrations visible. In the videotapes and post-session interviews, the students indicated that the visual nature of the representations were also useful in reducing their anxieties. The students positively evaluated the hints that were provided for each task.

- *Character Creation.* Students indicated that they enjoyed being an active character in the game and that this improved their ability to interact with the mathematics. Students wanted to control the character's gender, skin color, clothing, ethnicity, character name, and skills. This is a standard option in most MMRPGs. Students made numerous positive comments about details such as being able to see the characters breathe. They were greatly attracted by maneuvering their character arbitrarily in the virtual world and by character head motion, lateral motion, climbing stairs, walking underwater, etc. Interactivity with objects in the game environment is a crucial factor in gaining and maintaining student interest.
- *Concept Development.* Students demonstrated solution activity that indicated that they had developed their conceptions in important ways. Three of the students were able to complete the second problem pathway by building on their prior solution strategies for the previous problems. The students' problem solving activities and successes suggest that carefully crafted problem pathways can be a successful tool for encouraging students to build on their previous notions.

### Conclusions

Development and testing of the Phase II prototype is ongoing. The Phase II prototype includes more complex quest and help system structures, expanded mathematical quests, and additional avatars. A complete MMRPG will be developed in Phase III and only then can the full benefits of the game genre hope to be realized.

## EXPLORING THE PHENOMENON OF CLASSROOM CONNECTIVITY<sup>1</sup>

Stephen Hegedus

University of Massachusetts-Dartmouth  
jkaput@umassd.edu

James J. Kaput

University of Massachusetts-Dartmouth  
shegedus@umassd.edu

We describe highly generative and affectively powerful classroom activity structures that are made possible by applying new levels of connectivity across diverse hardware platforms. Based on teaching experiments involving core topics in basic algebra (slope-as-rate, linear functions, simultaneous conditions), we examine 3 kinds of activity structures exploiting a common display of student-produced mathematical objects: (1) Construction and sharing of personally meaningful and executable mathematical objects in “mathematical performances,” (2) Aggregation and display of student constructions that are systematically varied based on classroom social and/or physical structure, and (3) The *Where Am I?* aggregation activity structure, where students’ constructions are aggregated in ways that require students to perform careful analyses to “find themselves” in the aggregation. Strong learning achievement pre/post-test results suggest considerable promise in such activities, especially with low-performing students.

### Context and Aims of the Study

We are currently investigating the impacts and potentials of recent advances in connectivity technology in grades 7-9 mathematics classroom, particularly linking diverse hardware platforms such as the TI-83+ graphing calculators and larger computers.

The work builds on earlier SimCalc research (for summary see Roshelle et al., 2000) which aimed to democratize access to the Mathematics of Change and Variation underlying the Calculus (Kaput, 1994) using a variety of new representations, links to simulations and new curriculum materials. The software enables students to interact with animated objects whose motion is controlled by visually editable piece-wise or algebraically defined position and velocity functions. One form of the software has been developed for the TI-83+ (Calculator MathWorlds) and the other is a cross-platform Java application (Java MathWorlds) which exploits higher screen resolution, with the ability to pass MathWorlds documents between the two platforms—see [www.simcalc.umassd.edu](http://www.simcalc.umassd.edu) for further details. The new ingredient is classroom connectivity that enables students to share mathematical functions across diverse hardware platforms and teachers to collect, aggregate on a common classroom display, and otherwise work with students’ constructions on the teacher’s workstation, as well as to distribute functions to the students. Hence we combine the two root affordances of the computational medium, representation and communication.

In this paper, we describe the phenomenological space of a SimCalc connected mathematics classroom that arises from preliminary studies in the Spring and Fall Semesters of 2001, and more tightly controlled empirical work currently underway.

### **Theoretical Framework**

Classroom connectivity (CC) opens a large and richly endowed opportunity space for teaching, learning, assessment and curriculum activity design, a space jointly structured by the structures of mathematics, and the social and physical structures of the classroom in a dialectical relationship (Stroup, et al., these proceedings). The social structure plays a direct role in the structuring of mathematical activities, and vice-versa in a dialectical fashion. In some cases, the interplay of social and mathematical structures lead to an elevation of organization of mathematical structure, as when students organized into groups build functions that vary parametrically across the groups, yielding structured families of functions reflecting the structure of the classroom, an elevation of the organizational structure of the mathematical objects, from functions to families of functions. At the same time, the focus of student attention is likewise elevated to the level of what the group is doing rather than what the individual is doing. In addition, for certain of the activities that we explore, students' personal identities are intimately involved in their building and sharing of mathematical objects in the public space of the classroom. While in this brief paper we focus on teaching and new activity structures, we note that an enormous range of foundational educational issues are raised by CC because the radically increased bandwidth of CC, supporting the direct sharing of mathematical objects such as functions, directly affects the heart of what happens in classrooms, among students and between students and teacher. See our Discussion Group paper with Stroup, et al. (these Proceedings) for further discussion of our theoretical framework.

### **Technological Connectivity**

The prototype Navigator network from TI allows us to connect TI-83+ graphing calculators together. As many as four calculators, including the teacher's calculator, can be physically connected to a hub which wirelessly communicates to an Internet gateway in the classroom that in turn communicates with a remote server. This server acts as an active storage buffer between students and teacher. The teacher can also send and retrieve information and display received information on a standard TI-Viewscreen. This information includes Calculator MathWorlds documents. For example, a student can construct or edit a piece-wise defined position function and send it to the teacher who can then display the function, run its animation, and base a classroom discussion on it using the TI-83+ with ViewScreen.

Since Java MathWorlds can pass, collect and collate students' documents, the teacher can aggregate student constructions on the teacher's computer as well, including constructions produced on a computer rather than a graphing calculator and communicated via a standard computer network using standard intranet protocols. Finally, using the ability to pass MathWorlds documents between the two types of platforms, virtually any mix of the platforms can be used in the classroom (or computer laboratory). Our empirical work increasingly exploits these connectivity options.

### **Data Sources**

The ideas and data below reflect work in three venues, where we collected video data, field notes, and student work, as well as pre-post test data in 2 & 3. The mathematical topics across each venue included slope-as-rate, linear functions, simultaneous conditions, and modeling of linearly changing phenomena in both motion and non-motion contexts. In addition, in 2, we covered the full SimCalc curriculum, which involved rate-accumulation connections across a wide variety of rates of change and modeling contexts using graphical, algebraic and numerical descriptions. A fourth intensive teaching experiment was carried out with high-performing middle school students and which focused on peer-peer applications of connectivity, but will not be reviewed here.

1. We piloted the Navigator system in two local high school Algebra I classes in Spring 01 taught by their regular teacher (a SimCalc-experienced teacher). Topic:
2. We used a more stable form of the system in combination with a teacher workstation in a required year-long course taught by the PI at UMass-Dartmouth for 12 academically weak entering College Freshmen (who mathematically and demographically are comparable to typical urban high school algebra students).
3. We used a mix of calculators and computers in a 5 week Spring 02 after-school course for 35 grade 7-9 students in a second local high school taught by a SimCalc novice teacher from that school and assisted by two other SimCalc novice teachers. This course took place in a computer laboratory.

The first two venues helped generate and prototype activity structures that were then used more intensely in the 3rd. And since the 3rd also included pre-post test data where the majority of items were chosen from a required 10th grade state assessment, we will focus on task-types used in this intervention and follow with a brief summary of the results. Space limitations prevent transcript segments from sessions where these activities were utilized, but annotated video will be offered as part of the PME-NA presentation.

### **Three Basic Activity Structures**

We will illustrate three kinds of activity structures, each of which uses the social space of the classroom, and engages students' identities, in a different way. We will, however, limit the examples to topics associated with linear functions and slope-as-rate.

#### **(1) Creating and Sharing a Personally Meaningful Mathematical Object—Mathematical Performances**

This is a relatively simple type of activity, but one that we feel has enormous pedagogical potential because of the ways it taps into adolescent students' personal

experience, their personal identity, their need for recognition, and their creativity in expressing their unique personal experience. It also serves to focus class attention, which leads to opportunity for intense follow-up engagement by the teacher to exploit issues raised, for pedagogical and curricular purposes. We provide an example that was used across all venues using the TI-83+ version of MathWorlds and, with links to instructional material as well as graphics and student scripts illustrating the activity.

### Create an Exciting Sack Race That Ends in a Tie (Slope-As-Rate-of-Change)

We provide students the graph of a constant velocity position vs. time function which controls the (horizontal) screen motion of one object (A, the “car-like box” Above), which has the given constant velocity position vs. time graph in Figure 1 - A travels for 10 seconds at 2 m/sec. With the short stub of a starter-graph for B, we ask the student (1) to write a race-script for an “exciting race” with A; (2) to create a position vs. time graph for B that enacts the race; and (3) Send the race-document to the teacher who replays the race in front of the class on a large-screen display while the student author of the race “calls the race” by reading their narrative script as it runs.

We have seen both a large variety of uniquely personal student creations in response to this task and clear indicators of the “mathematical performance” aspects of the task—for example, in most cases, the classroom audience breaks into spontaneous applause when the race and story are complete. We offer a teacher’s model race for simplicity’s sake, and, in order to give a sense of how this activity is introduced to students, we embed the race-story in the form of directions to a teacher who is introducing the activity to a class. The teacher raises issues of steepness of line segments, zero slope, negative slope as well as intersection of function graphs and their interpretation as simultaneous position.

Imagine the teacher adding and adjusting one segment at a time (by stretching left or right and “tilting” it to adjust its slope) to produce the composite race shown in Figure 2 while asking a series of questions as follows. (i) Assume that B gets off to the

Figure 1.

Figure 2.

slow start as indicated by the first segment. Where is A relative to B at the end of that first segment? (ii) We want B to move faster than A and to pass A in a burst of speed. What slope do we need for our new (2<sup>nd</sup>) segment? (iii) Now, B went so fast he falls down! What kind of slope do we now need so that B does not move for 2 seconds? (iv) A has now caught up and is passing A, and B gets up confused and runs backward! What kind of a segment do I need now? (v) Finally, B gets an amazing burst of energy and finishes the race in a tie! How should I make my last segment? (This raises the issue of what a “tie” means graphically, etc.) Finally, the teacher runs the race and narrates it at the same time, to model what the students will be doing.

## **(2) Aggregation & Display of Student Constructions, Systematically Varied-Based on Classroom Structure**

Here the broad goal of this very general application of classroom connectivity is to generate and examine important mathematical structures and relationships, and to elevate the abstraction-level of mathematical attention from individual constructions to publicly displayed aggregates of these. The underlying idea is to engage students, or groups of students, in building mathematical objects that systematically vary in ways that depend on their place in the social (and perhaps physical) space of the classroom, and then to upload and aggregate these in a common classroom display. One obvious example is the elevation from functions to parametrically varying families of functions. While this vertical flexibility is a powerful pedagogical resource not only for supporting abstraction to parametrized families of objects but for many more general purposes, we will offer only a basic pair of examples.

### **A Flexible and Generative Group Structure for the Class**

Typically, the class is subdivided into groups, where the size of the group is determined by the teacher or activity designer to fit both the given size of the class and the mathematical activity (so the group might simply be the whole class, or each group might have only two members, meaning students are organized in pairs). Then the students count-off inside the group. In this way, each student has a two-number identity that then serves as the value of a “personal parameter” that thus systematically varies across students. The students then create mathematical objects that depend in some critical way on their respective parameter values and then upload these to the teacher where they are aggregated and displayed to the class. Sometimes important variation occurs within a group and sometimes across groups, depending on the activity designer’s learning objective and how (s)he chooses to tap into students’ identities (e.g., as colleagues, classmates, friends, fellow-sufferers, etc.) Moreover, if members of a group are physically adjacent, then varying the count-off number allows students to see the variation in their group’s productions. On the other hand, if we vary group number and not the count-off number, then group members are creating the same object and can help each other, be part of a team, etc. Again, choice of which to vary depends on the goals of the activity.

We will assume for our examples that students are formed into groups with 3-5 members, so each student has a count-off number ranging from 1 to 5, and the number of groups will depend on the size of the class, say 24 in this case.

Figure 3.

Figure 4.

### Linear Functions—The “Staggered-Start, Staggered Finish Race” (varying “b” in $y=mX+b$ )

In the simplest cases, students make a linear position vs. time  $Y=mX+b$  function where either  $m$  or  $b$  is their count-off number. In the latter, they make a 2 ft/sec motion defined by the position vs. time function  $Y=2X+b$  where “b” is their count-off number. We give  $Y=2X$  as a reference point. (Nobody has count-off number zero, although we can make activities where students subtract, say 3, from their count-off number, so someone gets to have parameter value equal to zero.) The resulting set of parallel lines and staggered starting points help reveal the invariance of slope (2 in this case), and how the systematically varying y-intercept relates to initial position. A companion activity involves using their group number as a starting point, so everyone in a group travels side-by-side, as shown in Figure 3, where we see the screen after 3 seconds of the 5 second race, and all persons in a group travel together. Furthermore, the position vs. time graphs of a given group are coincident, while the respective graphs of the 6 groups are all parallel. Lastly, in Figure 4 we can see the equation of each function and hence the parametric variation reflected in the seven values of “b” in  $y = 2X+b$

### Linear Functions—The “Staggered-Start, *Simultaneous Finish Race*”

In this activity, one dot (A) starts at 0 m and travels at 2 m/sec for 6 seconds. Each student starts at 3 times their group number and is to finish in a tie with A. Here each student in a group is solving the same problem, but may do so in many different ways. Furthermore, since the group numbers vary from 1 to 6, the starting points vary from 3 to 18, which means that the slopes of the graphs (see Figure 5) vary from positive, through 0, to negative, with all members of a group traveling together. The coefficients of  $X$  vary, along with  $b$ , descending by 1.5 as Group number increases from 1 to 6. Group 4, interestingly, starts at the “finish line” ( $3 \times 4 = 12$ ), has zero velocity, has  $X$  coefficient of 0, and has formula  $Y = 0X + 12$ . This strongly contextualizes  $Y = 12$  in a family of functions in 3 ways—algebraically, graphically and in terms of motion (where slope as rate of change is likewise in a central role). Groups 5 & 6 move backwards!

Figure 5.

ity at the mathematical heart of the activity via the student's personal projection of their identity into the publicly visible display – students and their peers quickly come to refer to the objects as directly indexing the members of the class, referring to a dot via a person's name, rather than indirectly (e.g., using phrases such as “John is ahead of Mary,” or “Is that you?” rather than indirect references such as “John's dot is ahead of Mary's dot,” or “Is that your dot?”

Our repeated experience with this activity structure convinces us that it has enormous power to energize a class, to focus students' attention on specific and important mathematical relationships and infuse it with affect based on the fact that students'

### (3) The *Where Am I?* Aggregation Activity Structure

In this genre of activities, both group and count-off numbers typically are allowed to vary, so each student in the class produces and sends up a unique object. However, the display of the aggregate is deliberately ambiguated to put the student in the position of needing to focus and reason in generally predictable ways to “find themselves” in the common display. We see two sources of pedagogical power in this type of activity: (1) The control of mathematical focus and reasoning based on the specific design of the activity (usually through the variation of representational elements), and (2) The engagement of the student's personal identity

personal identity is projected into the shared public space. We offer a simple example with linear functions.

### Linear Functions—Varying Starting Position (Group Number) and Velocity (Count-off Number)A

Start at your group number & go for 5 seconds at a velocity (whose numeric value is) equal to your count-off number.

- Which graph is yours? Explain your reasoning. (See Figure 6.)
- Based on *your motion only*, Where Are You? Explain your reasoning. (See Figure 7.)
- Which formula is yours? Explain your reasoning. (A list of all possible formulas is shown.)

In versions (a) and (c), respectively, students must relate the given initial position and velocity information to vertical intercept and slope of the graphs, or the constants in the formulas. In (b) they must relate the given initial position and velocity information to the motion, with the graphs hidden. Note that the teacher

has control of what information that is made visible to the students, hence can hide the graphs. In figure 6, we have displayed all the functions and representational elements simultaneously. However, we could display the motion with “Marks” dropped on a per-second basis, as shown Figure 7.

In Figure 6, we included an “outlier.” The potential role of errors is enhanced, as is the potential for student embarrassment—hence the teacher has the option of hiding any functions she chooses. We have seen great excitement and excellent logical reasoning occur as students attempt to track down the author of an erroneously produced object.

Figure 6.

Figure 7.

### Results and Conclusion: What Are We Learning?

A pre/post-test comparison for a 15 hour intervention with grade 7-9 students that applied the above activity structures as well as others involving simultaneous equations showed strongly significant gains on a battery of items drawn from a rigorous state 10<sup>th</sup> grade examination. Two thirds of the students were 9<sup>th</sup> graders who had previously failed or nearly failed the 8<sup>th</sup> grade version of the test a year earlier and the remaining students were 7<sup>th</sup> and 8<sup>th</sup> grade volunteers. All students gained on almost all items, and statistically strong gains summed across items for each of the groups. Of special note were strong gains on open-ended modeling items which most students find especially difficult.

We are in the very earliest stages of applying classroom connectivity and the illustrations offered above barely scratch the surface of what we foresee. As noted in Stroup, et al. (These Proceedings), the relationship between mathematical and classroom social structure has been radically strengthened, as has the potential for engaging aspects of students' identity and personality. Not only are our traditional expectations regarding classroom technology use being challenged, but our theories and accounts of teaching and learning are being challenged as well.

## THE DEVELOPMENT OF STUDENTS' KNOWLEDGE FOR GENERATING, USING, AND EVALUATING ALGEBRAIC REPRESENTATIONS OF LINEAR MOTION

Andrew Izsák  
The University of Georgia  
izsak@coe.uga.edu

Twelve pairs of 8<sup>th</sup>-grade students solved problems about a winch device that instantiated motions that can be modeled by pairs of linear functions. The paper examines how these students generated, evaluated, and refined initial algebraic representations to solve modeling problems. The findings extend previous research on algebra learning by providing further insights into ways that students must refine and reorganize understandings for constructing and using representations when moving from arithmetic to algebraic modeling and problem solving.

Understanding how students learn to represent and solve problems about “real world” situations is of practical and theoretical importance. Representing and solving problems about the surrounding world has always been central to mathematical thinking, and The National Council of Teachers of Mathematics (2000) has published standards that promote connections among mathematics, other disciplines, and the surrounding world. The *Standards* have led to curricula, including several funded by the National Science Foundation (e.g., Coxford et al., 1998; Lappan, Fey, Fitzgerald, Friel, & Phillips, 1998), that include modeling activities more varied than traditional word problems about boat trips up and down stream, mixtures of solutions with different concentrations, or other scenarios.

Although recent K-12 curricula place more emphasis on modeling, past research has documented numerous difficulties that students encounter when using algebraic, graphic, and other representations to model various contexts (e.g., Kieran, 1992; Leinhardt, Zaslavsky, & Stein, 1990). In summarizing past research, Kieran argued that learning to model with algebra is difficult because the representations are abstract and because the required operations conflict with those that students have learned to use through years of modeling with arithmetic. Kieran illustrated these differences using the following two problems.

*Arithmetic Word Problem.* Daniel went to visit his grandmother, who gave him \$1.50. Then he bought a book costing \$3.20. If he has \$2.30 left, how much money did he have before visiting his grandmother? (p. 393)

*Algebra Word Problem.* The Westmount Video Shop offers two rental plans. The first plan costs \$22.50 per year plus \$2.00 per video rented. The second plan offers a free membership for one year but charges \$3.25 per video rented. For what number of rental videos will these two plans cost exactly the same? (p. 393)

To solve the arithmetic problem, students first compute  $2.30 + 3.20 = 5.50$  to find how much money Daniel had after visiting his grandmother, and then extend this calculation by writing " $2.30 + 3.20 = 5.50 - 1.50 = 4.00$ " to find how much money Daniel had before visiting his grandmother. Three features of this solution are common to elementary-school students' approaches to modeling problems. (a) Students start with the amount that Daniel had at the end and work backward through the sequence of described events. (b) Students do not think that  $2.30 + 3.20$  and  $5.50 - 1.50$  represent the same number when writing " $2.30 + 3.20 = 5.50 - 1.50$ ." Instead, they interpret the equal sign as a command to compute  $2.30 + 3.20$  and then continue their calculations. (c) Students describe amounts of money that Daniel had at two particular times with the expressions  $2.30 + 3.20$  and  $5.50 - 1.50$ .

The following three features of a solution to the algebra problem contrast with those listed above for the solution to the arithmetic problem. (a') Students must work forward from the initial conditions to generate  $22.50 + 2.00x = 3.25x$ , which in turn requires students to reverse the mathematical operations that they previously used to model situations. (b') The equal sign in  $22.50 + 2.00x = 3.25x$  no longer expresses results of calculations, but a relationship between two expressions that holds for a unique value of  $x$ . (c') The expressions  $22.50 + 2.00x$  and  $3.25x$  do not express costs of specific numbers of videos, but rather costs of arbitrary numbers of videos. Kieran's analysis demonstrates how students must modify their existing understandings about generating and using representations when moving from modeling with arithmetic to modeling with algebra. The present study focuses on further modifications that have not been widely reported.

Although students' difficulties modeling with algebra are well documented, cognitive accounts of mathematical learning have focused more often on the construction of concepts than on the construction of knowledge for generating representations and solving problems. For example, an oft cited family of explanations for how students construct core algebraic concepts focuses on *processes* being *reified*, or *encapsulated*, into *objects* (e.g., Breidenbach, Dubinsky, Hawks, & Nichols, 1992; Sfard & Linchevski, 1994). Recently, a few studies have begun to focus on students constructing knowledge for modeling situations and solving problems. For example, Doerr and Tripp (1999) and Izsák (2000) have focused on equilibration among students' internal conceptual understandings, uses of external representations to solve problems, and understandings of modeled situations. This work has suggested that mathematical concepts are necessary, but not sufficient, for solving modeling problems. The research reported here analyzes in further detail how students can coordinate knowledge of representations and represented situations to construct new knowledge for solving modeling problems with algebra.

This article is grounded in the following definition of modeling:

*Mathematical modeling* consists of (a) examining various attributes of a particular mathematical, physical, or social context, (b) relating a subset of those

attributes through arithmetic operations, functions, or other mathematical structures, and (c) using resulting representations to solve problems.<sup>1</sup>

Parts (a) and (b) of the definition rely on the processes of *selecting attributes* and *relating attributes* (Izsák, 2000). The former refers to attending to a range of attributes and selecting a subset. The latter refers to combining attributes, for instance through addition or multiplication.<sup>2</sup> Part (c) refers to both internal and external representations. The example of imagined equations, graphs, or other artifacts can blur the distinction between internal and external representations because they are mentally held copies of external artifacts. The important distinction for this paper, however, is between artifacts, available either through imagination or perception, and knowledge for generating and using representations to solve problems. I reserve the word *representation* for external ones commonly used in mathematics or that students construct for themselves.

### The Study

In the spring of 1996 and 1997, I interviewed 12 pairs of eighth-grade students attending middle school in a middle-class city in the San Francisco Bay area. By interviewing students in pairs, I hoped to get rich verbal data on what students were doing, and why, without having to interrupt the flow of their problem solving very often. Most pairs consisted of friends who had prior experience working together, but two pairs consisted of students who did not know each other well. Nine pairs consisted of students taking their first algebra course. The course emphasized formal steps for solving different types of equations and inequalities and included a limited number of word problems about linear phenomena. Three pairs consisted of students taking a pre-algebra course that contained some work with variables and functions. Five pairs were girls, five were boys, and two were mixed.

The purpose of the interviews was to examine how students can construct algebraic models without direct instruction from more experienced others. In such cases, students must regulate processes by which they examine problem situations and generate representations with which to accomplish problem-solving goals. Such self-regulation is particularly complex when students do not have established strategies at hand for representing and solving problems.

Each pair of students came after school for four or five, hour-long sessions during which they solved problems about a winch device (see Figure 1) that instantiated motions that can be modeled by pairs of linear functions, a core topic in introductory algebra courses. I adapted the winch from similar devices used by Greeno (1993, 1995), Meira (1998), and Piaget, Grize, Szeminska, and Bang (1968/1977). The device had weights attached to two spools, one 3 inches and one 5 inches in circumference. I refer to these as the 3- and 5-inch weights, respectively. Depending on how the winch was set up, the weights could rise, fall, or move in opposite directions as students

turned the handle. A yardstick allowed students to measure heights of weights, changes in those heights, vertical distances between the weights, and changes in those distances.

The problems gave initial conditions for each weight and focused on three types of questions:

- (1) Predict the distance between the two weights after an arbitrary number of cranks.
- (2) Determine whether one weight will ever be twice as high as the other.
- (3) Determine whether the two weights will meet at the same height.

Some questions asked students to imagine a larger 100-inch winch. I did not specify how to answer the questions because I was interested in when students introduced and used representations, including algebraic ones, to solve the problems.

A key difference between more traditional algebra word problems, such as the video shop problem discussed above, and problems about the actual winch is that the winch questions did not give any linguistic cues about particular quantities that could be used to generate representations for solving the problems. In contrast, the text of the video shop problem directs students' attention toward the cost of each rental plan individually. Students are less likely to focus on the difference between the two costs and to ask when the difference is zero dollars, although this is a reasonable strategy for solving the problem. Thus, in general, the winch problems provided less scaffolding for students than do more standard word problems because students have to examine the problem situation—the winch—directly and decide for themselves which are the key attributes and how they might be related. Questions about the 100-inch winch did describe in words the initial conditions for each weight. For example, some questions stated that the 5-inch weight started by the 88-inch mark and dropped as the crank turned. In these cases, however, students had already worked with similar motions when answering earlier questions about the actual winch and thus had already built some understandings of the described phenomena by working with the winch directly.

The students engaged in concentrated problem solving during which they discussed the winch, a variety of problem-solving strategies, and refinements of those strategies. When students were working in this way, I intervened only on occasion to

Figure 1. The winch.

clarify my instructions, to ask for further explanation of some comment, or to discuss possible strategies for making progress when students seemed stuck. All students eventually introduced drawings, tables, and/or equations. I used two video cameras—one to record students and the winch and one to record the students' scratch paper.

I performed microgenetic analyses (Schoenfeld, Smith, & Arcavi, 1993) on the interview transcripts, which included notes about students' representations and actions with the winch. In particular, I examined students' utterances, hand gestures, actions with the winch, and written work for evidence of what they were thinking moment-by-moment. More often than not, data in a particular segment of transcript were open to multiple interpretations. I built cases for particular interpretations of individual segments by knitting local accounts into consistent, global ones of the knowledge that students accessed and grappled with as they solved problems about the winch. The level of analysis represents an observer's perspective on what was initially problematic from the students' point of view and what understandings students subsequently constructed.

### Analysis and Results

The theoretical framework summarized in Figure 2 emerged from analyses of the data. The frame is informed by theoretical perspectives on learning found in Smith, diSessa, and Roschelle (1993/1994) and Schoenfeld et al. (1993). These authors have described learning as the refinement and reorganization of prior knowledge useful in some contexts. The frame emphasizes the development of modeling knowledge as the emergence, refinement, and reorganization of knowledge for generating, using, and evaluating algebraic representations to accomplish problem-solving goals. The arrows represent reorganizations across the three categories of knowledge. This report focuses primarily on arrow 1, the arrow between *Evaluating Representations* and *Generating Representations*.

All 12 pairs of students answered questions of type 3—determine whether the two weights will meet at the same height—either by turning the handle or by generating equations smoothly. In contrast, students were unsure how to answer questions of types 1 and 2. Four pairs (all algebra students) generated, evaluated, and refined algebraic

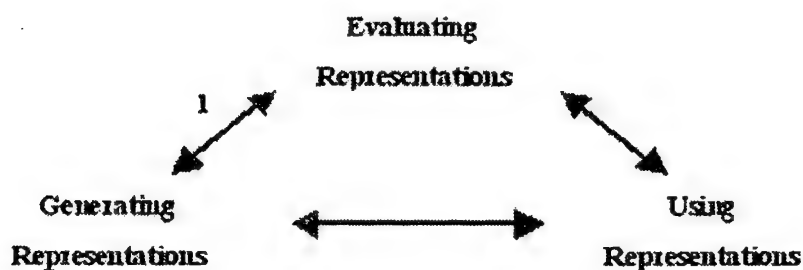

Figure 2. Developing knowledge for modeling with algebra.

representations as they worked on such questions. The analysis below emphasizes understandings that began to emerge as students evaluated and refined initial algebraic representations. The remaining pairs either generated no algebraic representations or generated equations and solved problems smoothly and quickly. Thus, these data did not provide access to students learning to model with algebra.

When the 3- and 5-inch weights started by the 14- and 0-inch marks, respectively, the 5-inch weight caught up to the 3-inch weight by the 35-inch mark after seven cranks. Pair 1 first represented the distance between the weights using  $14 - 2n$  before the two weights met, and  $2n$  after (See Figure 3. The subscripts in Figure 3 were added to clarify students' correspondences between symbols and winch attributes.). When using the first formula, the students thought of an initial 14-inch distance that decreased and counted cranks from the initial winch set-up. When using the second formula, the students thought of an initial 0-inch distance that increased and counted cranks from the place where the weights met. The students understood when to use each expression, and could substitute values to compute distances that matched measurements on the winch, but the students could not agree that the split approach was adequate for representing distances between the weights. A key understanding that

Figure 3. Pairs 1 and 2 generated, used, and evaluated algebraic representations for answering questions of type 1, predict the distance between the weights.

the students used for evaluating their split representation appeared to be *single equations*—the criterion that single equations are better than multiple ones. The students then reexamined the winch, focused on a new set of winch attributes, and generated the single  $|(n - 7) 2| = d$  equation. Using *single equation* to evaluate and refine initial algebraic representations of distances between the weights is an example of arrow 1.

Pair 1 used a similar *single equation* criterion when working on questions of type 2 (see Figure 4). When the 3- and 5-inch weights started by the 28- and 0-inch marks, respectively, the students first introduced a set of three equations. One equation expressed the height of the lower 5-inch weight, one equation expressed the distance between the two weights, and one equation equated the height of the lower weight with the distance between the weights. The set of three equations expressed correct relationships among the heights of each weight and the distance between them when the 3-inch weight was twice the height of the 5-inch weight. The students questioned their set of equations, however, explicitly stating “we want one equation.” They then generated, but also questioned,  $0 + 5n = 28 - 2n$  because it was not true for arbitrary numbers of cranks. The students experienced conflict between their *single equation* criterion and *always true*—the criterion that algebraic representations should be true for any value of the independent variable. For example, the students knew that their equation was not true for  $n = 1$ .

Eventually, after solving their equation and confirming the four crank solution using the winch, the students dropped *always true* in this context. Refining those situations in which to apply *always true* is a second example of students coordinating knowledge for generating algebraic representations and evaluating algebraic representations, arrow 1. This coordination emerged in large part because students were able to use their representation (in this case solve their equation) to solve the problem. Thus the data illustrated the other two arrows in Figure 2 as well:

Pairs 2, 3, and 4 evidenced further criteria for algebraic representations. These students initially constructed algebraic representations by relating all attributes that they found salient and relevant. I will refer to this understanding as the *include all attributes* criterion. Pair 2 predicted distances when an imagined 100-inch winch was set up so that the 3- and 5-inch weights started by the 28- and 0-inch marks, respectively (see Figure 3). These students explicitly articulated the correct understanding that half the current distance between the weights was the same as the number of remaining cranks till the weights met. The students expressed this understanding with the equation  $.5x = c$ . When I asked if they could use the number of completed cranks instead, the students generated  $14 - q = c$ , which expressed the correct relationship between the total number of cranks for the weights to meet, the number of completed cranks, and the number of remaining cranks till the weights met. I asked Pair 2 if they could use just one equation—thereby introducing something like Pair 1’s *single equation* criterion—and the students generated  $14 - q = .5x$ . They questioned their new equation, however, apparently thinking that  $c$ , the number of cranks till the weights met, should

Figure 4. Pairs 1, 3, and 4 generated, used, and evaluated algebraic representations for answering questions of type 2, will one weight ever be twice as high as the other.

be represented explicitly because it was central to their understanding of the changing distances between the two weights. Only after substituting for  $q$  and calculating  $x$  did they realize that  $14 - q = .5x$  combined a sufficient set of attributes to determine the distance between the weights. With new understandings about using their equation to determine distances, the students dropped *include all attributes* in this context (a third example of arrow 1 and an example of the other two arrows in Figure 2).

Pairs 3 and 4 evidenced a similar *include all attributes* criterion when working on questions of type 2 (see Figure 4). When the 3- and 5-inch weights started by the 14- and 0-inch marks, respectively, both pairs generated initial algebraic representations that expressed correct relationships among heights of both weights and distances between them. In the case of Pair 3, this is easier to see if one introduces parentheses:  $x - (14 - 2n) = y$ . These students began with the higher height and subtracted the distance to get the lower height. Pair 4 first equated the distance between the weights with the height of the lower weight and then doubled the lower height to get the higher height, generating in order  $14 - 2x = b$ ,  $14 - 2x = (2b = s)$ , and then  $(14 - 2x = 2b) = s$ . The students in Pair 3 questioned the number of variables in their representation, and the students in Pair 4 questioned the number of equal signs in theirs. Although both pairs focused only on heights when introducing subsequent equations that did not have the same problems (see Figure 4), neither pair could solve their equations and so did not understand that their new approaches would work. In their work, Pair 1 may also have used an *include all attributes* understanding, but they did not express it as clearly. In contrast to Pair 1, the inability of Pairs 3 and 4 to use equations that they had generated may have blocked refinement of the contexts in which they applied criteria. Thus these data also pointed to important interactions between students' knowledge for generating, using, and evaluating algebraic representations as they tried to solve modeling problems.

### Conclusion

The analyses above showed that students have knowledge for evaluating algebraic representations, and that they can use such knowledge to refine initial representations as they solve modeling problems. At the same time, the data did not provide access to the origins of criteria like *single equation*, *always true*, and *include all quantities*. A plausible hypothesis is that students construct such understandings through repeated experiences representing and solving addition and subtraction word problems, expressing linear patterns with "rules," and other experiences. For example, most addition and subtraction word problems require students to use all of the included information. The arithmetic word problem about Daniel discussed above is a prime example. Through solving such problems, students may develop an implicit, if not explicit, understandings that all relevant information should be included in representations of problem situations. Data from the present study suggests that students may continue to apply this understanding as they model situations in which subsets of salient attributes are suffi-

cient for solving problems, and in which including all salient attributes, in fact, blocks solutions. Similarly, rules for linear patterns are usually expressed as single formulae that are true for all values of the independent variable. Through repeated experiences with such tasks, students may again develop and implicit, if not explicit, understanding about what makes a good algebraic representation for solving a problem. Students may carry this understanding inappropriately to new problem-solving situations where they need to generate equations that constrain the independent variable to a unique value. These hypotheses about the origins of students' criteria for algebraic representations extend Kieran's (1992) observation, cited above, that students have to refine and reorganize relationships they construct between representations and problem situations that afford algebraic solutions to problems.

I did not collect classroom data as part of this study, and so cannot say whether the interviewed students had had opportunities in class to discuss and compare different relationships between representations and modeled situations. Nevertheless, analysis of the data suggested that more explicit and extensive discussions focused on the ways that representations are generated and used to solve modeling problems could have helped these students to examine their existing understandings for modeling with algebra and to construct new understandings more quickly.

### Notes

<sup>1</sup>Doerr and Tripp (1999) provided a similar definition of modeling, and English and Halford (1995) provided a compatible definition in the case where the problem situation is presented through text.

<sup>2</sup>Thompson's (1994) *quantitative operations* are similar to *relating attributes*.

# **A STUDY OF THE CONVERSION FROM TABLE TO GRAPH: SELECTING THE TYPE OF GRAPH ACCORDING TO THE CONTEXT OF THE PROBLEM**

Simon Mochon & Patricia Maroto Cabrera  
Center for Research and Advanced Studies, IPN, Mexico  
smochona@sni.conacyt.mx

This paper presents the results of a research study which had as its main objective to investigate students' conversions from a table to a graph, where the underlying situation provides the meaning and therefore the suitability of the type of graph. We describe the responses of a group of nineteen students in a pedagogical university to a "constructing graph" and a "choosing graph" questionnaire, and to the interviews that followed. The analysis showed the students' difficulties to differentiate between continuous and discrete variables and how to represent them appropriately. We observed in general an overuse of bar charts and polygonal lines. The students also had difficulties distinguishing between the different types of graphs.

## **Introduction and Theoretical Framework**

In many circumstances it is very important to choose the appropriate graph that represents a given real situation. A different type of graph might lead to a wrong interpretation of the information being conveyed. To start with, a continuous (discrete) situation should be represented by a continuous (discrete) type graph. But within continuous and discrete graphs, there are different forms which would be more suitable to a given situation. In a spreadsheet for example, when constructing a graph we need to choose among several types of graphs. Consequently, we advanced a research project which has as its main objective to find out what types of graphs students associate with different types of word situations.

There has been a large research effort studying students' conceptualizations of functional relationships and their difficulties in interpreting graphs (e.g., Chazan, 1994; Dugdale, 1993; Kaput, 1993; Kieran, 1993; Schwartz & Yerushalmy, 1995; Yerushalmy, 1994). Some of these authors have studied how students construct graphical representation from "mathematizing activities." Although in this project we were also interested in the construction of a graph from a given problematic situation, the ultimate purpose was different. We were interested in finding out what types of graphs were selected to represent different type situations and how well they are correlated. We also wanted to observe the difficulties in performing these tasks.

Although math functions (equations) usually correspond to smooth continuous graphs, in real type situations the corresponding graphs could be of many different types. To cite an important example, the SimCalc project, directed by Dr. James Kaput gives a graphical approach to the ideas of Calculus, through an educational software package called "MathWorlds." The basic graphing elements of this software are step

and polygonal graphs. Thus, these are two additional types of graphs we considered in this study.

The topic of representations has been given widespread attention in the mathematical education research. As suggested by Duval (1993), the coordination of registers in different representations is crucial for the understanding of the related concepts and is by no means natural. Embedded in this conversion is the issue of congruence. The general problem we are interested in is the “congruence” between the tabular and graphic representations. However, we focus on a different aspect of congruency. Since a table is inherently discrete, it is seldom equivalent to a graphical representation. This implicit lack of congruency can be a source of students’ difficulties in converting from one to the other. We need then a description of the situation to aid on the conversion from table to graph. In this research, we study the translation process from a table of values within a word problem to a graph and the effect of the type of situation in the graph selected.

### Methodology

We considered in our research five types of problem situations (see the Appendix) according to five different types of graphs: two continuous (a smooth curve and a polygonal line); two discrete (a points graph and a bar chart) and one “hybrid” (a step graph).

We designed two questionnaires. The first one contained five construction type problems in which the most suitable graph was to be drawn according to the situation described (the appendix shows these construction problems). Each problem represented a different type of situation and therefore a different type of graph. The first problem corresponded to a polygonal line. The second problem related to a discrete situation and therefore corresponded either to a point graph or a bar chart. The third problem had intervals where the variable stayed constant and thus a step graph was the best choice. The fourth problem described a continuous situation. The fifth problem was a frequency distribution and thus was best described with a bar chart.

The second questionnaire contained five *election* type problems in which the best graph describing the situation had to be chosen from five graphs attached to the problem. All these five graphs, each one from the five types described above, were designed to represent the problem as best as possible (the questions on this second questionnaire were similar to the ones on the first questionnaire and therefore are not included in this paper).

In all the problems, the statement of the problem was accompanied by a table of values. The purpose of this was to observe if the students restricted themselves to the values given on the table, or completed the necessary information from the problem.

The two questionnaires were applied to 19 students of education at a pedagogical university (future secondary school math teachers) after their first year of study (completing their basic math training). After the answers to the questionnaires were

analyzed, five subjects were selected (on the basis of representative and interesting work) for an interview to probe their ideas further.

The analysis of the questionnaires and interviews focused on the type of graph chosen, with special attention to the students' difficulties in the conversion tasks.

### Results and Conclusions

In the first problem of the construction questionnaire (see appendix) the dependent variable (amount of water) is a continuous quantity and the rates of filling and emptying are stated as constants, which means that a polygonal line would be the best choice to represent this situation.

To give an overall idea of the choice of graphs, they were classified into five groups, according to the five types described before. The graphs drawn by the students in this problem were: eight polygonal lines, two smooth curves, two point graphs and seven bar charts.

The four graphs shown on this page were drawn by students for this first problem. In the first graph (in the upper-left corner), the student tried to connect the points so that “only one  $y$  corresponds to each  $x$ ” but because the axes were inverted, this was impossible. The second graph (in the upper-right corner) also has the axes inverted. The values of the amount of water were taken only as labels for the  $x$ -axis (0, 100, 100 and 0), so it is evident that the information from the statement was ignored and the graph was drawn from the values of the table alone. The other two graphs can serve as contrast. The one in the bottom-left corner was drawn taking into account only the data in the table. The other one, in the bottom-right corner, was constructed by adding important information from the statement of the problem. It is evident that the first three graphs are far from representing the situation they originated from. In other words, it would be almost impossible to reproduce the problem situation from the graph. The fourth graph on the other hand, although not the “correct” type, conveys the situation much better.

In general, only very few of the graphs within the polygonal type (the correct choice for this situation) represented the problem posed in an adequate way.

The second problem has a characteristic discrete time and therefore either of the two discrete graphs (point graph or bar chart) would fit the problem. The graphs drawn by the students in this problem were: 12 bar charts, five polygonal and two with points. This is almost a “perfect” match since polygonal lines are also often used to represent discrete variations. We have to mention however that some of the bar charts are confusing to read since their labels were put in the boundary between the bars (like a real axis) and therefore it is not clear which of the two adjacent bars gives the correct value.

The third problem is better represented by a step graph because the time is considered as continuous but the charges of money made are constant through each whole hour. The graphs drawn by the students in this problem were: nine bar charts, seven polygonal and three with points. A complete mismatch. Two of the graphs are reproduced below.

The graph on the left is a bar chart and the one on the right a polygonal that turned out to be a straight line (the student even wrote, "The growth goes in a linear manner"). We emphasize again that these two graphs, as all the others drawn for this situation, were bad descriptions of the problem being represented.

The fourth problem referred to a situation in which the quantity of fertilizer can change continuously, so a smooth graph was the best representation. The graphs drawn by the students here were: seven polygonal, six bar charts, three smooth curves and two with points. Again a bad mismatch. This is very surprising because continuous graphs are used constantly in math and science instruction, so we would expect the students would prefer these type of graphs. It is also interesting to observe that a third of the graphs in this problem had inverted axes. This hints again that the students based their graphs from the table of values and not the statement of the problem, because only from the latter can be extracted which is the independent and dependent variables.

The fifth problem is a frequency distribution of a discrete variable, so either the bar chart or the point graph would be the best choice. The graphs drawn by the students here were: 10 bar charts, 7 polygonal and 2 with points. This is again almost a perfect match (considering the polygonals as acceptable).

Thus, we can observe in general an overuse of bar charts and polygonal lines. However, both of these graphs were used indistinctly in all types of problems and not with the expressed intention to match the behavior of the situation. Due to this, we can observe that the discrete problems had a much better proper matching than the others. The worst matching was done in the smooth and step type problems.

The following table summarizes the totals of the types of graphs selected in all problems combined. The first remark in the above paragraph (an overuse of bar charts and polygonal lines) can be seen clearly in the results of this table. As we mentioned before, surprisingly enough, there were very few smooth continuous curves. Step graphs were really not known by the students, although many real life situations behave in this fashion.

| Type of graph selected (Totals): |           |           |           |          |
|----------------------------------|-----------|-----------|-----------|----------|
| Smooth                           | Polygonal | Points    | Bar chart | Step     |
| <b>5</b>                         | <b>34</b> | <b>11</b> | <b>44</b> | <b>0</b> |

The results of the second questionnaire, the election type problems, are summarized in the following table:

| Type of graph elected (Totals): |           |           |           |          |
|---------------------------------|-----------|-----------|-----------|----------|
| Smooth                          | Polygonal | Points    | Bar chart | Step     |
| <b>19</b>                       | <b>17</b> | <b>11</b> | <b>36</b> | <b>6</b> |

It is interesting to contrast these two tables. When the students were shown the five types of graphs associated with each problem (second table), they elected in a

higher proportion than before the smooth curves. Also, the step graphs were chosen some of the times. This obviously produced a drop on polygonal and bar charts selected, compared with the previous results. These numbers suggest that smooth curves are not drawn naturally, but, if they are provided as options, can be recognized as better descriptions of continuous problems (on the continuous type problem, half the students elected the continuous graph as the best choice).

The graphs drawn in the interviews followed the same patterns summarized above in the questionnaires. However, there were some interesting additional observations that are described below.

We noticed that there is confusion between discrete and continuous variables. In fact, when continuous graphs were read by the students, they only paid attention to their integer values. Surprisingly enough (because in math instruction, graphs are generally smooth), in continuous type problems, the students often used point graphs or polygonal lines. Two students remarked: "I don't use continuous curves" and "I don't like to draw curved graphs".

The students commented that they don't see a difference between the smooth and the polygonal graphs. Actually, they explained that they preferred the polygonal graphs because they could see the changes better. (One student commented: "I join the points to see if it moves back," and "in the curve, I don't find well the points.") Also, they did not distinguish between the polygonal and the points graphs. One student said: "... is like the polygonal but you don't join the points."

With respect to step graphs, the students have difficulty conceiving horizontal parts of graphs. They actually perceive them as bar charts (several students commented that "... it is very similar to a bar chart"). When they were given a different situation with a constant rate (like a velocity), they tended to graph instead its accumulation (the distance).

We studied here the connection between the statement of a problem, an attached table, and the corresponding graph. We observed throughout this study that there is confusion between discrete and continuous variables and how to represent them correctly (the discrete type graphs are clearly overused). This is due only in part to fact that part or most of the information about the variation of the quantities is contained in the statement of the problem and this is often ignored. But more importantly, even when taking into account the statement, the students did not know how to differentiate between the different types of graphs.

Although this research was exploratory in nature with subjects taken from a group of future teachers, we expect these same results for math teachers in general. Thus, it suggests already that in instruction, we don't pay enough attention to distinguish between the different types of graphs available and how these correspond to different types of situations. These are very important ideas that need further research with many kinds of subjects, because we constantly use graphs to convey information, and we should be able to reconstruct the situation entirely from the corresponding graph.

### Appendix

In this appendix, we reproduce the five problems used in the construction questionnaire (the tables in the real questionnaire were vertically oriented instead of horizontally as done below).

The five figures in the next page show the corresponding best fitting graph for each of these five problems.

1. A tank to store water is initially empty. During two hours, it is filled at a constant rate of  $50 \text{ m}^3$  per hour. In the next three hours it is maintained closed. Right after this, it is emptied at a constant rate of  $25 \text{ m}^3$  per hour. The next table registers the amount of water in the tank:

|                                   |   |     |     |   |
|-----------------------------------|---|-----|-----|---|
| Time (hours):                     | 0 | 2   | 5   | 9 |
| Amount of water ( $\text{m}^3$ ): | 0 | 100 | 100 | 0 |

2. During seven days, there was an exposition of the work of a sculptor. The number of people attending the exhibition hall was registered every day. The following table shows this data:

|                     |     |     |     |     |    |    |     |
|---------------------|-----|-----|-----|-----|----|----|-----|
| Day:                | 1   | 2   | 3   | 4   | 5  | 6  | 7   |
| Number of visitors: | 531 | 689 | 203 | 100 | 50 | 45 | 200 |

3. In a parking lot, the charge is \$8.00 for an hour or a fraction of it. Thus, if the car is there for less than an hour, the charge is \$8.00; if the car is there up to two hours, the charge is \$16.00 and so forth. This is shown in the following table:

|                 |   |    |    |    |    |
|-----------------|---|----|----|----|----|
| Complete hours: | 1 | 2  | 3  | 4  | 5  |
| Cost (\$):      | 8 | 16 | 24 | 32 | 40 |

4. A farmer wants to know how much fertilizer is the optimum for his field of tomato plants. For this, he applies different amounts of fertilizer and counts the number of tomatoes produced. The results he obtained are shown in the table below:

|                       |     |     |     |     |     |
|-----------------------|-----|-----|-----|-----|-----|
| Amount of fertilizer: | 0   | 100 | 150 | 250 | 450 |
| Number of tomatoes:   | 300 | 425 | 600 | 800 | 650 |

5. In a demographic study, a poll was taken to 50 women about the number of children they bear. The data registered is given in the following table:

|                |   |   |   |   |   |   |   |   |   |
|----------------|---|---|---|---|---|---|---|---|---|
| # of children: | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| # of cases:    | 1 | 3 | 6 | 7 | 9 | 7 | 8 | 4 | 5 |

## **SIMULATION OF AN ACTUAL CONTEXT AND ITS ALGEBRAIC REPRESENTATION**

José Alberto Monzoy Vásquez

Hugo Rogelio Mejía Velasco  
Departamento de Matemática Educativa  
del Cinvestav-IPN, México  
hmejia@mail.cinvestav.mx

The main purpose of the research study presented in this paper was to analyze how simulating an actual context and the coordinated work between the simulation and the tabular and graphic representations of a concept modify the meaning of the algebraic representation of that concept. For that purpose, we chose the concept of function, emphasizing the concept of linear function. We developed specific software for this research. This software simulates an actual context—filling containers—and allows the interaction with the graphic and tabular registers of representation. Duval's contributions to the study of representation registers of a mathematical object were a fundamental basis for designing the software and the research instruments. (Duval, 1998; 1999) One outstanding result was that most participants in this research study, through the activities of simulating the actual situation of filling containers, could give meaning to the slope of a linear function.

### **Theoretical Background**

The characteristic feature of mathematical concepts, to be considered as such, is their high degree of abstractness. For instance, the mathematical concepts of variable and function can be considered as “the abstract generalization of concrete variables (such as time, distance, velocity, angle of rotation, and area of surface traced out) and of the interdependences among them (the distance depends on the time and so forth)” (Aleksandrov, Kolmogorov, & Lavrent'ev, 1956/1999, p. 43). Hence, the conceptual appropriation of a mathematical object is achieved by identifying its distinctive properties. However, we can only have access to a mathematical concept by means of its representations. These representations themselves reflect only part of the properties of the concept.

Duval called this contradiction a cognitive paradox of the mathematical thought. He stated his proposal to solve it as follows: “The coordination of various registers of semiotic representation appears itself as fundamental for a conceptual apprehension of objects: it is necessary that the object be not confused with its representations and that it be recognized in each of its possible representations.” (Duval, 1998, p.175) The coordination of registers of representation refers to mobilizing several registers of semiotic representation, being able to choose one register instead of another, and switching from one to another representation during the same intellectual course. (Duval, 1999)

From the viewpoint of cognitive activities propitiated by representations, a semiotic system is a register of representation if it makes possible the following three activities:

The formation of an identifiable representation based on a selection of features and data of the content to be represented.

The treatment of a representation, which is the transformation of another representation, in the register itself where it has been formed.

The conversion: transforming a representation of one register into the representation of another register keeping the whole or just a portion of the content of the initial representation. (Duval, 1998, pp. 177-178)

Incorporating computers, as an additional element, into the teaching and learning of mathematics processes opens new perspectives for students to achieve the conceptual apprehension of mathematical objects. Furthermore, the use of computers as a means to representing mathematical objects has made concepts to obtain a more diverse and deeper meaning. Access to representations has been widened (Tall, 1996). Computers have the capacity of bringing about treatments in representations, such as the graphic and tabular ones, to the level where such treatments acquire sense and meaning beyond the simple exemplification of static forms of algebraic representations. In a great variety of systems of representation, the action of the user changes the physical state of the representation (Kaput, 1994). 'Complex' activities of conversion with paper and pencil can also be carried out in a more accessible way (Mejía, 1996). From these considerations, the simulation of an actual context has been interpreted as a register of representation of one concept: the actual register.

### **The Simulation Tool**

The actual context is implemented by the software called Recipientes [Spanish for Containers] (Monzoy, in preparation). The simulation of filling containers—a rectangular prism, a cylinder, and a truncated cone—is built into this software by establishing the geometric characteristics of the variables to be studied: filling volume, area of the transversal section, and filling level. Additionally, from the implicit mathematical model of the established functional relations in the simulation, the software implements the activities of identification, treatment, and conversion in the tabular and graphic systems. A typical window is shown in figure 1.

The activities are carried out in the registers by the intervention of the user. For instance: (a) in the actual register, it is possible to modify the dimensions of the containers, whether with the mouse or by assigning values to them; (b) in the tabular register, the menu option Tools—Analyze Table opens a window in which the quotient of increments can be computed, and the extreme values of the table and the increment in the column corresponding to the filling level can be modified; and (c) in the activities

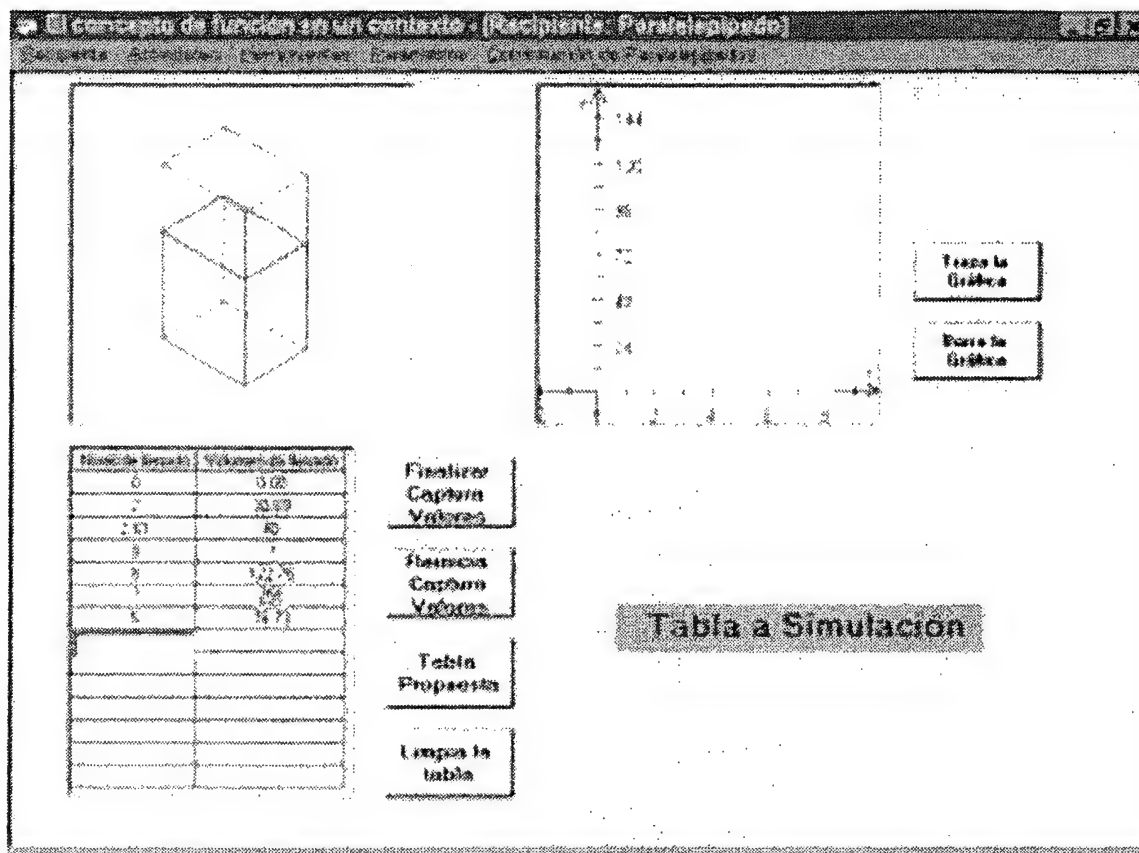

Figure 1. A window of the software Recipientes.

of conversion, the user can choose the two involved registers so that the activities in the initial register are manifested in the final register.

### Methodology

The research study was carried out with 15 students (ages 15 to 17) who had completed the first and second grade courses of mathematics in higher secondary school (grades 10 and 11). They had studied the algebraic representation of the concept of linear function. Most of them had not passed in the second grade course of mathematics and, according to the teacher, "they were close to" passing in the course.

These were the stages of the research study:

1. Application of a test before the work with Recipientes. This pretest contained questions about identification in the tabular and graphic registers, and about situations such as obtaining the algebraic expression from a table, from the graph of the linear function, or from the representation of a physical context in a coordinate system (distance traveled by an automobile). For instance, two of the questions were:

- (a) The values of a linear function, with independent variable  $x$ , dependent variable  $y$ , and domain the interval  $[-4,4]$  are given in the following table. Write the algebraic expression of the function.

Table 1

| $X$ | $Y$ |
|-----|-----|
| -4  | -7  |
| -3  | -5  |
| -2  | -3  |
| -1  | -1  |
| 0   | 1   |
| 1   | 3   |
| 2   | 5   |
| 3   | 7   |
| 4   | 9   |

- (b) The two graphs plotted in the coordinate system represent the relation of distance to time, of the movement of two cars: car A and car B. The distance is measured in kilometers and the time, in hours.
- Obtain the algebraic expression for the straight line that shows the movement of car A.
  - Obtain the algebraic expression for the straight line that shows the movement of car B.

Figure 1

2. Students worked with the software *Recipientes* during four sessions of about 2 hours and 20 minutes each. The activities in these sessions were done using work sheets. During the first two sessions, the *training* tasks with the software were carried out. For example, participants had to obtain the dimensions of a parallelepiped, being given a table representing the relation between the filling level and the filling volume. During the third session, the instructor explained the terms 'independent' and 'dependent variable' and showed a procedure to obtaining the algebraic expression from a table and a graph. In the next work sheets, tasks that required a more open work with the software were indicated. That is, activities such as obtaining the algebraic expression of a linear function from the conditions of a container or from a table or a graph; or obtaining the dimensions of a parallelepiped from an algebraic expression which modeled the process of filling the container. An example of this type of questioning is the following:

It is known that the algebraic expression that establishes the relation between the independent variable  $h$  and the dependent variable  $V$  of the filling process of a parallelepiped is

$$V = 35 h, \text{ with domain } [0,10].$$

Obtain the dimensions of a parallelepiped that satisfies the given algebraic relation of the filling process. Plot the corresponding graph and indicate the range of the function.

3. Application of a test after the work with *Recipientes*. This test was elaborated essentially the same way as the pretest.
4. Interviews with three participants. The purpose of the interviews was to confirm some results regarding the use of the software, and the responses given by the participants in the work sheets were the basis for formulating interview questions.

### Analyses of Results

The activities of converting a table or a graph into an algebraic expression in the work sheets were done correctly by 60% of participants. Those who did not obtain the correct answer could obtain the value of the slope although they made mistakes in the algebraic operations.

The activities of obtaining the dimensions and the graph given the algebraic expression of the filling process of a container were done correctly by all participants. These results and the way in which participants obtained the answers suggest that the work with the simulation of filling a container did not provoke inconsistencies and that participants adopted it naturally for working with the concept of linear function.

Regarding results of the pretest and the posttest, there was a considerable increase in the number of participants who answered correctly the questions of the posttest referring to obtaining the algebraic expression of a linear function associated to condi-

**Table 2.** Results From the Pretest and the Posttest

| Initial register  | Final register | Pretest | Posttest |
|---|----------------|---------|----------|
| Tabular   | Algebraic      | 0       | 7        |
| Graphic   | Algebraic      | 0       | 7        |
| Graphic (context modeled by a graph that crosses the origin)        | Algebraic      | 0       | 9        |
| Graphic (context modeled by a graph that does not cross the origin) | Algebraic      | 0       | 6        |

tions given by a table, a graph, or a context. Results as to number of correct answers are shown in table 2. The situation that participants did not answer correctly the questions of the posttest but could compute the slope, making mistakes in algebraic manipulations, was different from the situation in the pretest, in which only two participants tried to answer the analogous questions.

The interviews with three participants were video-recorded for a better retrieval of information for this research. These interviews were done to precise how the actual register was used for obtaining the algebraic expression. Questions used for the interviews were based on results written in the work sheets. Interviewees had access to the software *Recipientes* during the interviews.

When we asked the first interviewee how she had obtained the algebraic expression from a table, her answer was not given immediately and, pointing to the monitor screen, she said: "The height and the filling level are used and they are divided."

Even though her assertion is not correct, she tried to base it on the actual register. Then, to the question "What data would you look for in the graph to find the quotient?", regarding how to obtain the algebraic expression from a graph, this first interviewee answered: "The value of  $x$ , the value of  $y$ ."

Thus, she was asked to use the software to find the values she mentioned. She used the window of simulation to reflect it on the graph; she clicked on the filling level of the container and indicated that that is represented in the graph. She did not remember the procedure for obtaining the algebraic expression.

When she used the window of simulation, she tried to base her work on more concrete situations; she could obtain these from the actual register. Moreover, she did not restrict herself to working in a single register. That is, although she was asked to establish the algebraic expression from the graph, she used simulation.

The second interviewee was also asked about the procedure for obtaining the algebraic expression from the information given in a table. She answered: "I did not use the software because what was asked for was algebraic. Thus, I took two values... and so on." She pointed to the procedure used in the work sheet, which was correct. Then, she said: "I did use the software to see the quotient of differences, which is 20 in

this case.” Therefore, in this situation she used the software to check her results, doing activities of treatment in the table.

Then, when this interviewee was asked how to obtain the algebraic expression from a graph of the linear function, shown on the computer screen, and which corresponded to the work sheet, she answered: “It’s the same but in another way. I took two values... First, I searched with the software... the dimensions of the container. I took the values from there. [She pointed to the table on the monitor screen.]

The behavior of this participant during the interview allowed to observe that the actual situation simulated with the software was an important basis for obtaining the data required to find the algebraic expression. Moreover, she showed that her activity with the software was not limited to a single register, but, on the contrary, that she was able to use the different registers available in the software. She used these different registers to check her assertions or to obtain the data she needed to use.

The third interviewee was nervous during the interview in spite that she knew well how to handle the software, in contrast with the other two interviewees. As to the question on how the algebraic expression is obtained from a table, she answered: “You take two values and make subtractions with those beside them.” Then she explained the operations she had carried out to find the answer required in the corresponding work sheet—her answer was correct. Following, she was asked how to get from the graph the data needed to obtain the algebraic expression. She indicated: “The points with which the graph is plotted.” The interview process was stopped because, on the one hand, her answer in the work sheet was correct and, on the other hand, the interviewee was getting increasingly nervous.

From the analyses of the interviews, we can conclude that participants exhibited a wider and more consistent interpretation of the algebraic expression from the filling of containers. Besides, when using the different registers built up with the software *Recipientes*, and selecting the register which was considered the most appropriate to solve the problem, they exhibited that they did coordinate the actual, tabular, graphic, and algebraic representations.

### **Discussion and Conclusions**

No contradictory results were found in the analyses of the answers—right and wrong—to the pretest and the posttest, the responses in the work sheets, and the interviews. Hence, working with the software *Recipientes*—being one of its features the incorporation of the simulation as a register of representation—it is possible to obtain a wider and consistent meaning for the algebraic representation of the concept of linear function.

Results from the analyses of the work sheets and the answers to the posttest, which were verified through the interviews, also showed that the software *Recipientes* made it possible for participants to get a more concrete meaning of the slope of a linear function. Additionally, the interviews showed that the simulation of filling containers

was an important support for the participants' assertions. This situation suggests that this physical referent supports the coordination of the actual, tabular, and graph registers of the concept of function and allows a favorable modification of the meaning of its algebraic representation. Besides, the relation between the variables and the dimensions of the containers did not provoke confusions.

This didactical experience afforded evidence that the incorporation of the simulation of an actual context as a register of representation is very helpful. Now, it is necessary to investigate whether the simulation of different actual contexts representing the same concept supports generalization aspects.

This study investigated seventh- and eighth-grade students' ( $N = 90$ ) abilities to solve problems using tabular, graphical, verbal, and symbolic representations and to translate among these representations before and after instruction. Students experienced more success solving problems using a given representation than translating among representations, with success strongly influenced by the particular representational formats involved. Performance improved with instruction, with the greatest gains occurring with an experimental curriculum (*Bridging Instruction*) that explicitly built on students' invented strategies and representations. Results suggest there are significant gaps between students' abilities to comprehend and to produce representations, that students may attain fluency with instance-based representations (tables and point-wise graphs) before holistic representations (symbolic equations and verbal expressions), and that instruction that explicitly bridges from students' intuitions about quantitative relations can enhance students' abilities to work within and translate among various representations.

One important aspect of mathematical competence is the ability to reason with and among multiple representations. The National Council of Teachers of Mathematics (2000) calls for an increased focus on a variety of mathematical representations, including graphs, tables, symbolic expressions, and verbal expressions, as well as the interconnections among them. These skills, which we call *representational fluency*, are growing in importance as the mathematics education community struggles to reform algebra instruction and curricula.

Despite the documented need for and benefits of representational fluency (e.g., Kaput, 1989), little is known about students' abilities to solve problems presented with different representations or to translate among different representations. This study investigated these issues as well as the impact of a theoretically guided approach for classroom instruction aimed at the development of algebraic reasoning in the middle grades. Specifically, we investigated 4 research questions:

1. How is initial student problem-solving performance influenced by representational format?

2. How is representation use during problem solving influenced by instruction?
3. How well can beginning algebra students initially translate among representations?
4. How is fluency among representations influenced by instruction?

### **Theoretical Framework**

Motivated by the need for sustained, in-school research on students' representation use, this study was carried out in a classroom setting. It compared the influences of a theoretically guided experimental curriculum (described below) and *Connected Mathematics* (CM; Lappan, et al., 1998a, 1998b), a reform-based middle school mathematics curriculum shown to be effective (Hoover, Zawojewski, & Ridgway, 1997). CM emphasizes collaborative, discussion-oriented activities that use data gathering and representation as well as problem solving to make mathematics conceptually meaningful to students. Because it also addresses connections among mathematical representations, and because it was widely used at the school site under investigation, CM served as the control curriculum for this study.

The experimental curriculum implemented in this study, *Bridging Instruction* (BI), grew out of prior research on students' algebraic reasoning that showed the prevalence and power of students' informal and invented problem-solving strategies (Hall, Kibler, Wenger & Truxaw, 1989; Kieran, 1988, 1992; Koedinger & Nathan, 1999; Koedinger, Alibali, & Nathan, 2002; Nathan & Koedinger, 2000a, 2000b; Tabachneck et al., 1994) and their promise for supporting deep, conceptual understanding of more advanced mathematics (e.g., Nathan & Koedinger, 2000c). Like CM, BI takes a collaborative, problem-based approach to mathematics education. However, BI starts by eliciting students' invented strategies and representations and explicitly *bridges* from these to more formal and more efficient solution methods during classroom discussion. Thus, students' intuitive notions of how to organize data, how to depict them pictorially, and how to describe both linear and nonlinear relationships in words serve as precursors to their use of tables, graphs, and equations, respectively.

### **Method and Data Sources**

Ninety students in four combined 7th/8th grade mathematics classrooms in a middle/upper-middle class school district in the Midwestern U.S. participated in this study for 9 weeks. Two of the classrooms were designated control classrooms and implemented CM, the school's standard curriculum, while the other two classrooms implemented the experimental curriculum, BI. The same, regular classroom teacher taught all four classes.

The CM curriculum is well described (Lappan, Fey, Fitzgerald, Friel & Phillips, 1998a, b) and commercially available. Students in the CM (control) condition worked through the seventh-grade units *Variables and Patterns* and *Moving Straight Ahead* during the time of this study.

The BI curriculum approached bridging in several ways. First, students' invented solution strategies and representations served as conceptual bridges to more formal procedures and representations. In prior studies (e.g., Nathan & Koedinger, 2000c) middle school students were observed using various invented solution methods to solve story problems and systems of equations. Guess-and-Test is one such method that students intuitively apply. It serves as a powerful inroad into formal algorithms because it highlights the structural aspects of the algebraic relations (Kieran, 1992) and procedurally grounds the concept of variable. Throughout the 9-week intervention, BI students were called upon to first decide for themselves, individually or in small groups, how they would represent data or solve for unknown values.

For example, in a variant of the "bridges and pennies" task (week 1; adapted from CM 8th grade series), students were asked to make a table to record the thickness of a paper bridge and the number of pennies that just breaks that bridge. They were then given wide latitude to graph the relationship between bridge thickness and number of pennies. Many insights emerged about students' understandings of graphical representations from the public displays of their graphs. Students did have a general understanding of the need for axes, labels, and plotted points, but did not all agree on how to label axes. Discussions of scale and interval size, and of the nature of dependent and independent variables naturally emerged. Students also did not all treat the independent variable (bridge thickness) as continuous. Many groups only included the values for which there were data collected, treating bridge thickness initially as nominal. This led to important discussions of the similarity of an axis to a number line. Finally, when students were asked to interpret their graphs, many read off relations like one would read values from a table. This led to the idea that one could use a line of best fit instead of the individual points to find an overall relationship between bridge thickness and bridge strength (measured in pennies).

In a second aspect of bridging instruction, concrete analogs served to ground more abstract representations. For example, in the "building squares" activity (week 3), students investigated the relationship between the side length and area of a square by building squares out of 1-inch square tiles. To see how area grows as a function of side-length, students used a method described by Kalchman (1998). Students decomposed the squares, stacked the tiles along grids of 1-inch graph paper, and marked off the values (heights) that showed the number of square-inches covered by each square. This provided a concrete way for students to both record the area of each square and to see how that area could be represented as the height along an axis of a graph.

In a third aspect of BI, linear and nonlinear relations served as contrasting cases for one another in order to make properties of each more salient to learners. In "building squares," students were explicitly asked to observe how both area and total tile perimeter (the sum of the side-lengths of all the tiles) grew as a function of the side-length of the squares, and to describe verbally and visually how these two growth patterns were similar and different. This idea was expanded further in "the cube problem"

(weeks 8 and 9) in which the growth patterns for corner pieces (constant function), edge pieces (linear), face pieces (quadratic), and hidden pieces (cubic) were described and compared visually, verbally, and symbolically as functions of the side-length of the entire cube. One reason to use contrasting cases during instruction is to help learners form differentiated knowledge structures (e.g., D. Schwartz & Bransford, 1998). Linear functions are often taken as prototypical exemplars of functions. This can have detrimental effects on students' learning because linear functions have some unique attributes that do not generalize to all mathematical functions, such as (a) linear functions form a straight line when graphed against linear axes; (b) only two points are needed to determine a linear function; (c) the rate of change is constant; (d) missing values can be determined through linear interpolation and extrapolation (B. Schwartz & Hershkowitz, 1999). Most students, in fact, over-generalize the properties of linear functions and make erroneous assumptions on the basis of these over-generalizations, such as believing that only one function (a line) can pass between two given points. BI students directly confronted some of these misconceptions by simultaneously considering linear and non-linear functions throughout their algebra unit.

Classroom instruction and student interactions will be described in detail in future reports. Here we report on students' abilities to work within a given representation and to translate among representations, as assessed before and after the two different 9-week instructional interventions. The assessment instrument used a factorial design to allow systematic examination of the effects of problem linearity (linear or exponential), slope-sign (increasing or decreasing function), input representation (graph, symbolic, or word expression), and input-to-output translation (a graph, symbolic, or word expression input paired with a graph, table, symbolic, or word expression output) on student performance.

All problems given in the assessments were first introduced in words. Problems then presented the "input" representation (i.e., a graph, symbolic, or word expression) and asked students to respond to two problem-solving items and one translation item. The problem-solving items required students to work within the given representation to find a specific value of the dependent variable given a specific value of the independent variable or vice versa. The translation items required students to represent the presented functional relationship using a different output representation. Appendix 1 illustrates the multiple forms a linear problem could take given the variety of input and output representations involved.

## **Results and Discussion**

### **Students' Initial Problem-Solving Performance**

Pretest results indicate that linearity and mathematical representations do indeed influence students' problem-solving performance (see Figure 1). Problem-solving performance using graphical representations greatly exceeded that of all other repre-

sentations. This graphical advantage held regardless of slope-sign (i.e., increasing or decreasing) for both linear ( $M = 86.0\%$ ,  $SD = 12.7\%$ ) and nonlinear ( $M = 85.3\%$ ,  $SD = 12.2\%$ ) functions.

In addition, students performed better on linear ( $M = 58.3\%$ ,  $SD = 32.1\%$ ) than nonlinear ( $M = 39.7\%$ ,  $SD = 36.0\%$ ) problems,  $F(1, 68) = 47.50$ ,  $p < 0.0001$ . The interaction of linearity and representation was also significant,  $F(2, 28) = 20.76$ ,  $p < 0.0001$ . Students experienced more success on linear problems when provided a verbal representation than when provided a symbolic one (linear word:  $M = 65.1\%$ ,  $SD = 22.3\%$ ; linear symbolic:  $M = 24.0\%$ ,  $SD = 21.0\%$ ), whereas symbolic representations led to greater success than verbal representations on nonlinear problems (nonlinear symbolic:  $M = 20.8\%$ ,  $SD = 19.8\%$ ; nonlinear word:  $M = 13.0\%$ ,  $SD = 12.3\%$ ; see Figure 1). This replicates the complexity-representation interaction reported by Koedinger et al. (2002) showing that verbal representations are most effective when solving lower complexity problems, whereas symbolic representations are more effective for higher complexity problems.

Figure 1. Proportion of problem-solving pretest items solved correctly by problem representation and linearity.

### Influences of Instruction on Problem Solving

BI students made greater gains in problem-solving performance from pretest to posttest than CM students (see Table 1), yielding a significant date by condition interaction,  $F(1, 68) = 4.01$ ,  $p = 0.05$ , with CM students' improvements -limited to linear functions presented symbolically. Negative CM gains were not statistically different from zero. In contrast, BI gains were distributed across all representational formats and all levels of linearity.

**Table 1.** Proportion of Problem-Solving Pretest and Posttest Items Solved Correctly Along With Test Gains, Organized by Representational Input, Linearity, and Instructional Condition

| Input Representation → |          | Graph  |           | Symbol |           | Word   |           |
|------------------------|----------|--------|-----------|--------|-----------|--------|-----------|
| Instruction ↓          |          | Linear | Nonlinear | Linear | Nonlinear | Linear | Nonlinear |
| Control<br>(CM)        | Pretest  | 0.85   | 0.87      | 0.29   | 0.24      | 0.72   | 0.17      |
|                        | Posttest | 0.77   | 0.77      | 0.47   | 0.28      | 0.61   | 0.15      |
|                        | Gain     | -0.08  | -0.10     | 0.18   | 0.04      | -0.11  | -0.02     |
| Experimental<br>(BI)   | Pretest  | 0.87   | 0.84      | 0.19   | 0.18      | 0.58   | 0.09      |
|                        | Posttest | 0.88   | 0.90      | 0.39   | 0.25      | 0.67   | 0.32      |

### Students' Initial Translation Performance

Translation among representations appears to be a very advanced skill. At pretest, translation performance was essentially at zero for all but a few types of problems (see Table 2). Students could use pre-constructed input representations to solve problems (Table 1) far better than they could generate new representations as a part of a translation task. In the most dramatic example, pre-constructed graphs were correctly used for problem solving more than 80% of the time, but students across conditions could only correctly produce them about 6% of the time during translation tasks.

**Table 2.** Proportion of Translation Pretest and Posttest Items Solved Correctly Along With Test Gains, Organized by Representational Input and Instructional Condition

| Output Representation → |          | Graph | Symbol | Table | Word |
|-------------------------|----------|-------|--------|-------|------|
| Instruction ↓           |          |       |        |       |      |
| Control<br>(CM)         | Pretest  | 0.11  | 0.19   | 0.11  | 0.02 |
|                         | Posttest | 0.10  | 0.10   | 0.34  | 0.05 |
|                         | Gain     | -0.01 | -0.09  | 0.23  | 0.03 |
| Experimental<br>(BI)    | Pretest  | 0.00  | 0.12   | 0.12  | 0.06 |
|                         | Posttest | 0.30  | 0.13   | 0.38  | 0.21 |
|                         | Gain     | 0.30  | 0.01   | 0.26  | 0.15 |

### Influences of Instruction on Representational Fluency

Overall, students were more successful on the translation items at posttest than at pretest,  $F(1, 68) = 42.86, p < 0.0001$ , though post-instruction performance was still low in both conditions (Table 2). BI students made greater translation gains than

CM students,  $F(1, 68) = 5.94$ ,  $p = 0.02$ . The CM group experienced a 5.6% increase in correct responses, while the BI group experienced a 17.6% increase. Negative CM gains were not statistically different from zero. By posttest, CM students could translate from any input representation to a table of values at a rate significantly greater than zero while BI students could translate from any of the input representations to a table of values and to a graph, and could also translate between word expressions and symbolic equations.

Students understood and produced instance-based representations (i.e., tables and point-wise graphs) far better than more holistic representations (symbolic and verbal expressions, and line graphs). Graphs present an interesting case within the instance-based/holistic dimension, because they can be either instance-based (as with scatter plots and bar graphs) or holistic (as with line graphs). This duality does not apply to symbolic expressions, word expressions, or tables of values. To further understand students' performance with representations along this dimension, we compared experimental students' post-intervention abilities to produce accurate graphs when they were judged with instance-based versus holistic scoring criteria. An instance-based graph was defined as one including at least three correct data points. It was not necessary for the axes to be labeled with words or for the points to be connected with a line or exponential curve. Holistic graphs were ones in which the function (line or exponential curve) was drawn and the correct y-intercept was included. When evaluated from the point-wise perspective, students exhibited relatively high levels of performance ( $M = 29.5\%$ ). When they were evaluated using holistic criteria, performance was much lower ( $M = 4.3\%$ ). However, even when students constructed instance-based graphs, they often made other types of errors (see Figure 2).

## Conclusions

This study documents students' pre-instructional knowledge of mathematical representations and the effects of instruction on representational fluency. Students' pre- and post-instructional problem solving was heavily influenced by representational format, with students succeeding much more often with graphical representations than with symbolic or verbal representations, for both linear and nonlinear problems. On linear problems, students succeeded more often with verbal representations than with symbolic representations, and on nonlinear patterns, this pattern was reversed. This finding replicates earlier research showing a trade-off among representations, such that verbal representations are more

Figure 2. Point-wise graph of function  $d = 1200 - 40n$

effective for simpler problems, whereas symbolic representations are more effective for more complex problems (Koedinger, et al., 2002).

Our findings are consistent with Kalchman, Moss, and Case's (2001; Kalchman, 1998) psychological theory of the development of children's understanding of mathematical functions, which holds that procedurally based (i.e., computational) representations (e.g., tables of instances) and analogical representations (e.g., bar graphs) developmentally precede and form the basis for the more integrative, holistic representations (e.g., line graphs). In the translation tasks used in this study, students were most successful at generating tables of values. They were also more successful at generating instance-based graphs (e.g., scatterplots) than at generating holistic graphs (e.g., line graphs).

Pedagogically, one plausible hypothesis is that tables and instance-based graphs are a natural entry point into the mathematics of covariation, which serves as a central idea for the mathematics of functions. Because of their dual nature, graphs may be particularly effective in helping students to bridge from instance-based to more holistic representations. Ultimately, they may help students to learn the more holistic formalisms and to reap the rewards of such formalisms in the face of increasingly complex (e.g., nonlinear) relationships.

This study also demonstrated that *Bridging Instruction* was effective at facilitating both problem solving and translation. Why was *Bridging Instruction* so successful? One possibility is that the approach provides conceptual grounding for the meanings of various algebraic representations, by explicitly connecting them to students' informal reasoning and their intuitions about data organization and quantitative relations. This conceptual grounding may serve to support representational fluency. Another possibility is that it is pedagogically valuable to address linear and nonlinear functions within the same instructional unit. Each type of function can serve as a contrasting case for the other, reinforcing important common concepts while highlighting important distinctions. The present study does not allow for definitive conclusions about the individual or combined effects of bridging from students' informal reasoning or of teaching linear and non-linear functions in tandem. Future studies of each of these factors will be needed to tease out the basis for the effects we have observed. However, at a minimum, the present work documents that an instructional approach grounded in students' informal reasoning, and focused on both linear and nonlinear functions, can be highly effective and suggests that such instruction deserves greater consideration in the classroom.

## WHAT PROVIDES SUPPORT FOR STUDENTS' UNDERSTANDING OF SYSTEMS OF LINEAR EQUATIONS?

Susan D. Nickerson  
San Diego State University  
Snickers@sunstroke.sdsu.edu

In previous studies of students' understanding of systems of equations, researchers have speculated on how a particular instructional approach to graphs of linear equations affected students' understandings of systems of equations (cf., Goldenberg, 1988; Kieran, 1996; Sfard & Linchevski, 1994). To systematically explore this question, this investigation involved an 8-week classroom teaching experiment in a high school algebra classroom. The classroom teacher and I designed two technology-intensive instructional sequences. After the teacher taught each lesson, we met to discuss students' interpretations and revisions to plans for subsequent classes. The situated perspective was used to analyze the collective mathematical development of the class and to compare ways in which individuals participated in the collective development. From an analysis of the evolution of mathematical practices and students' conceptions as they participated in them, I have identified four key aspects of students' experiences with graphs of linear equations that supported their understanding of systems of equations.

Few studies specifically document students' understanding of systems of linear equations. On the one hand, Goldenberg (1988) and Sfard & Linchevski (1994) have hypothesized how students' prior experience with linear functions did not support students' understanding of a solution to a system as a single point, an infinite number of points, or no points. For example, students often think of a variable as representing only a fixed unknown value and they encounter difficulties when solving systems of equations where the system consists of coincident or parallel lines. On the other hand, Yerushalmy and Schwartz (1993) and Kieran (1996) have reported how a particular approach to linear functions supported students' understanding, specifically with regards to visualizing graphs of functions. Kieran (1996) reported that with a particular approach to linear functions variables were more readily interpreted as variables rather than a fixed unknown.

This study systematically explored how a particular instructional approach to graphs of linear equations affected students' understanding of systems of equations. As part of an 8-week classroom teaching experiment, I worked with a high school teacher to design two instructional sequences—one for graphs of linear functions and one for solving systems of linear equations. We had several instructional goals. Among them was a goal of strengthening students' conception of a line as a set of points and its slope as a rate of change. Another goal was to support students' efforts to construct robust notions of the relationship between two quantities so that they could move freely between algebraic and graphical representations of this relationship. In an effort

to support their understanding of systems of equations, we had a specific goal that students develop an awareness that a variable can be interpreted as more than a fixed unknown. Furthermore, with these goals in mind we inverted the traditional approach of an introduction to linear functions without a contextual base to one strongly situated in context. In addition to an analysis with regards to these instructional goals, the research described here attempts to account for social context, the role of students' personal experiences with various phenomenologies, and the role of language in the construction of socially-shared meaning.

### **Theoretical Perspective**

In this study, I combined analyses of individual student learning with analyses of the social milieu in which this learning occurred. This investigation took individual students' reasoning as a unit of analysis while simultaneously viewing that reasoning as an act of participation in communal practices. This study used the situated perspective to analyze the collective mathematical development of the class and to compare the ways in which individuals participated in the collective development. In order to describe the collective development, the construct of a practice was used to examine the structure, responsibilities, and common activities of the mathematics classroom. Practices do not dictate a way to participate but are a description of the collective activity that arises from each student's interpretations of the social norms and socio-mathematical norms of a culture (Cobb & Bowers, 1999).

According to theorists of the situated perspective, knowing mathematics is considered an aspect of participation in social practices. Learning implies becoming a different person with respect to relationships in a community (Lave & Wenger, 1991). In particular, one can describe a student's learning of mathematics in terms of a trajectory of participation in the practices of mathematical discourse and thinking (Boaler & Greeno, 2000). I described four target students' individual growth in terms of their trajectory of participation in the classroom practices.

### **Setting**

The participants attended a suburban high school yet about one-third of the students resided outside of the high school's attendance area. Twenty-seven percent of the students qualified for free or reduced lunch. The Algebra I class consisted of 34 students in ninth through twelfth grades. Approximately 20% of the class was classified as LEP (Limited English Proficient). Ten students were repeating the course as a result of having failed it on earlier attempts. The teacher had ten years experience teaching high school and was proficient with technology. She valued a classroom where students were expected to reason about mathematics and communicate their thinking to others in the classroom. The students met in a computer lab for just under half of the number of class periods.

### **Methodology**

The methodology of this research was that of a classroom teaching experiment as described by Cobb (2000). The teacher and I developed a hypothetical learning trajectory based on how the collective mathematical activity might develop and by anticipating of the different ways in which students might participate in these activities (Simon, 1995). The high school teacher taught all the classes and I observed each lesson. After each day's lesson, we met to discuss students' interpretations and the implications for subsequent lessons. Furthermore, I interviewed four target students prior to and following each instructional unit, for a total of four times. There was a gap of two months between the two instructional interventions.

An interpretive framework developed by Cobb, Gravemeijer, Yackel, McClain, & Whitenack (1997) guided the analysis. This framework examines norms, socio-mathematical norms, and mathematical practices while simultaneously considering individual correlates. At the end of the teaching experiment, I identified phases that defined mathematical practices and shifts in socio-mathematical norms. This involved inferring taken-as-shared meanings of the collective and interpretations of individual students. I described how the classroom participants' contributions collectively constitute the evolving mathematical practices.

I also examined individual students' differing forms of participation in these practices. The four target students were the basis of case study analyses regarding three mathematical strands: their developing conceptions of speed as a rate, their evolving view of line graphs, and their representational activity. I further characterized their trajectory of participation in terms of their intellectual autonomy. Autonomy can be thought of as the degree to which students construct personal ways of judging (Yackel & Cobb, 1996). Increasing intellectual autonomy can be cast as students' evolution from reliance on a teacher's judgement of a mathematically acceptable answer with relatively little participation to increasing reliance on their own judgements (Lave & Wenger, 1991).

### **Data Sources**

The data sources drew from classroom lessons, interviews with four target students, and planning and reflection meetings. The data corpus consisted of:

- 1) videotapes of whole class discussions,
- 2) videotapes of small groups in which target students participated,
- 3) fieldnotes regarding the small groups that did not include target students,
- 4) all the students' written work,
- 5) pre- and posttests given to the entire class prior to and following each instructional unit, and
- 6) interview data from the four target students.

The videotapes of whole class discussions, videotapes and fieldnotes of small group activity, and all the students' written work were used to identify practices. The target students' written work, interviews, and participation in whole class and small group discussions were used to examine their developing conceptions and to describe their trajectory of participation.

### Overview of the Instructional Activities

One fundamental hypothesis in formulating our hypothetical learning trajectory was that we could build on students' pre-existing experience and understanding of motion to support their understanding of graphs of linear functions. We planned to use their experience with motion to help support several of our instructional goals.

Students began by trying to create target graphs using a motion detector hooked up to a computer. Students then wrote mathematical narratives for position graphs and predicted position graphs for given mathematical narratives. Students used SimCalc MathWorlds computer software to create position graphs that would simulate the motion for a character (Kaput, 1996). SimCalc MathWorlds is linked-representation software developed by a team of researchers to help students link formal representations with the experientially-real world (See Figure 1). Rather than focusing on a data set with a variety of symbolizations, SimCalc's focus is on the phenomenon, specifically motion (Kaput & Roschelle, 1997). SimCalc software enables students to explore motion with any combination of three graphs (position vs. time, velocity v. time, and acceleration v. time). Each of these can be linked to a character's motion, to each other, to a table of values, and to algebraic equations.

Figure 1. Interface of SimCalc MathWorlds software.

Over the course of the next couple weeks, students wrote equations for lines, explored the relationship among different representations (algebraic equations, position graphs, tables, and motion). They justified whether a given coordinate point was on a line. Students further gained experience interpreting rate of change and the y-intercept in contexts other than motion. They examined and created tables of values for determining a point of intersection, slope, and y-intercept. Finally, they solved systems by graphing, substitution, and by linear combination using other software developed for this purpose.

### Results

These four mathematical practices emerged over the two months of the teaching experiment:

- 1) Describing a line graph in terms of a character's speed and direction
- 2) Describing speed as a pattern
- 3) Viewing slope as constant for a line
- 4) Using slope to determine if two lines meet

The first practice, describing a line graph in terms of a character's speed and direction, emerged as students described a character's motion by means of comparison. Initially, whole class discussions focused on negotiating what counted as an acceptable description of motion. Students wrote mathematical narratives for graphs of position. We then asked students what a position graph would look like for a character's simulated motion. These activities encouraged students to attend to specific points--a character's beginning and ending distances and time elapsed for a journey. SimCalc software's depiction of a journey with piecewise linear graphs probably provided support for students' tendency to focus on "completed journey" rather than an on-going one. As anticipated, students' narratives for position graphs were initially framed in terms of a walker moving forwards or backwards and fast or slow, but were not framed in terms of distances from the motion detector over time. Line graphs were interpreted comparatively and in terms of speed and direction. The taken-as-shared understanding of speed was with regards to the overall relationship between quantities (distance and time). Students described the effect of time and distance on speed. For example, "He ran back twice the speed because he went twice the distance in the same time. He'd be going twice as fast." Students did not initially have a perspective of a line graph as a set of points. Thompson & Thompson (1992) have noted that in order to develop a sophisticated understanding of speed as a rate, students first conceptualize distance and time as constituent quantities, which is an important first step to making a multiplicative comparison between two fixed quantities.

The second practice, describing speed as a pattern, evolved as students came to describe position graphs as a collection of points that revealed aspects of the story. One

of our assumptions was that the learning of graphing entailed the refinement of visual, kinesthetic and narrative experiential domains (Nemirovsky, Tierney, & Wright, 1998). As students participated in the second practice, they indicated in the way they justified and in their symbolizing the graph of the line that they were thinking of speed in terms of an additive pattern. Justifications for speed consisted of language such as "You add three each time." When plotting points, students were able to identify patterns which they linked to writing the algebraic equation. Students connected patterns in a table of values with the algebraic equation. However, an analysis of practices indicated that students did not view slope as a rate of change.

The third practice, viewing slope as constant for a line, involved a shift to a view of slope as indicating a relationship between  $x$  and  $y$  coordinates. Students had been able to make a multiplicative comparison between the quantities of distance and time for a completed journey ("his speed is six meters in five seconds"). Upon realizing that students were having difficulty articulating a unit rate, the teacher posed a problem in which she asked students to examine a table of values and to determine where two characters met. The table recorded changes in  $x$  and  $y$  values that, like the former example of six meters in five seconds, involved non-integral slope. Students began to articulate a relationship between  $x$  and  $y$  values. A critical discussion involving a view of speed expressed as a unit factor initiated an evolution of practices. Furthermore, when graphing a line, students went from plotting multiple points to plotting two or three points. Students' language was suggestive of rate (e.g., "...for every one second, he moves 3 meters instead of 1.")

The fourth practice, using slope to determine if two lines meet, evolved from the practice of seeing slope as constant for a line. Once students saw rate as constant for the line. The taken-as-shared way of describing a line was uniquely determined by slope and intercept. Students looked at the equations of two lines and used information about slope and intercept to determine whether the two equations represented the same line, parallel lines, or intersecting lines. In the following discussion, as a follow-up to a student's comment, the teacher had asked, "What are all the possibilities for the graphs of two lines? What could happen if I graph two lines on the same set of axes?" Several students summarized for her the possibilities: parallel lines, same line, and intersecting lines. She asked for an example of two equations that represented the same line. One student, Cathy, suggested  $3x + 2y = 6$  and  $6x + 4y = 12$ . Another student offered another example in which the coefficients and the constant term of the second equation were a constant multiple of the coefficients and constant term of the first equation. Knowing the difficulty students had with fractions, the teacher asked if they could write an equation that was the same as  $y = (1/3)x + 5$ . Evan suggested  $y = (2/6)x + 10$ . Walter said, "He's only doubled one thing." Much discussion ensued regarding slope. Finally the teacher brought them back to the original question.

T: So, for  $y = (1/3)x + 5$ ?

M:  $y = (2/6)x + 5$  is the same line?

T: Yes. Why is that the same line? Aibi, did I multiply anything? What has stayed the same? Let's talk about what has stayed the same.

W: The fractions are the same. [referring to the slope]

C: The starting point is the same.

T: Oh, starting position, which is the same as what?

Ss: y-intercept.

T: That's how we'll know, besides doubling and tripling it, if it is the same line for sure.

C: Like Anisha says. They are the same thing. One-third equals two-sixths. There's no difference there.

T: True, True.

M:  $3y = x + 15$ . That you get by multiplying.

T: Yes, Jesus. What's the slope [of the line  $3y = x + 15$ ]?

J: One-third.

T: y-intercept?

J: Five.

[...]

T: Carlos, what do we need to determine if two lines are the same?

C: Get them like y equals something.

Students used information about slope and intercept to determine whether the two equations represented the same line, parallel lines, or intersecting lines. As the students solved systems of equations, the students indicated that they could estimate or compute the intersection of two lines based on rate of change. For example, when justifying how a target student knew two lines were parallel, he replied, "They'll never meet. The rate at which they grow is the same." Another target student would explicitly state how they each changed and stated the intersection in terms of "catching up."

### Discussion and Conclusion

From an examination of mathematical practices, which describe the collective mathematical development of the class, I identified four key aspects of students' experiences with graphs of linear equations that appear to have supported their understanding of systems of equations and the nature of solutions to systems of equations:

- a) Encountering line graphs situated in the context of motion
- b) Engaging in point-wise interpretations of a line graph
- c) Understanding that a line is uniquely determined by slope and intercept
- d) Negotiating the nature of the socio-mathematical norms for justification

An analysis of the evolution of mathematical practices and students' conceptions as they participated in them indicated that students' work strongly situated in the context of motion did support their efforts to solve problems without a contextual base. Their prior activity of defining lines as sets of points in concert with work situated in the context of motion supported their efforts to construct meaning for the solution to a system as a single point, no points, or an infinite number of points. Their experiences enabled them to conceive of a solution as points that lie on both graphed lines and simultaneously satisfy both equations. The conception of a line as uniquely determined by slope and intercept supported their knowledge of equivalent equations and their interpretation of coincident lines as a solution to a system. Finally, the social norms and the nature of the whole-class ways of justifying can be linked to students' construction of meaning of systems of equations. The evolution of mathematical practices can be linked to particular social and socio-mathematical norms.

Encountering line graphs situated in the context of motion meant that students saw the solution to a system first in terms of two people meeting--in other words, two people being at the same place at the same time. Students who had a sophisticated understanding of rate used justifications that folded back to language about "catching up" as they described changing distance between graphs. Situating line graphs initially in the context of motion meant that students equated the  $x$  values with time and this supported awareness that a variable could represent an infinite number of values and not just a single unknown. This supported their construction of meaning for solutions to a system.

Engaging in point-wise interpretations of a line graph enabled students to construct a taken-as-shared meaning of a point of intersection in terms of a shared point. This enabled a view of lines as a set of points and they were able to conceive of a point of intersection that lies on both graphed lines and simultaneously satisfies both equations.

As described earlier, understanding that a line is uniquely determined by slope and intercept enabled students to determine whether two lines were equivalent, parallel, or intersecting at one point. Students used this knowledge of equivalent equations in solving systems by linear combination and in their interpretation of coincident lines as a solution to a system.

Finally, another key aspect of students' experiences with graphs of a linear equation involved the nature of what counted as an acceptable justification. The social norms and whole-class ways of justifying can be linked to students' construction of

meaning of systems. The analysis revealed the importance of particular social norms, such as students explaining their answers and the expectation that they question an explanation if they did not understand. The negotiation of socio-mathematical norms was critical in the evolution of practices as the teacher helped the students formulate what counted as an acceptable explanation.

By situating individuals in the emerging practices of a mathematics classroom, I was able to contrast students who were participating at one level with other students who were becoming more central participants. Groups of students participated in the same practices but experienced whole-class conversations differently. The results portrayed how students' different forms of participation were affected, in part, by their conception of speed as a rate, by their participation in prior practices, and by their participation in the practices of other classes (e.g., concurrently taking a physics class). For example, as illustrated above, one target student with a less sophisticated image of rate experienced pivotal whole-class discussions about slope and intercept uniquely determining a line as being about how to arrange an equation in a format that would help identify critical elements.

With this work, we have a paradigmatic case of the situated perspective applied to a high school classroom. Through an examination of four individual students' trajectories of participation, I was able to situate students' changing interpretations as they participated in the evolving mathematical practices. This work also informs classroom teachers in that it embraces the complexity of the classroom. It accounts for what students and teachers contribute to the evolving community of practice. Analyses such as this can help teachers, curriculum developers and software designers anticipate ways in which other students will negotiate meaning.

# **SUPPORTING LATINO STUDENTS' LEARNING IN EIGHTH GRADE ALGEBRA: USAGE OF LANGUAGE FOR UNDERSTANDING EQUIVALENCE**

Nancy O'Rode  
University of California at Santa Barbara  
onancy@education.ucsb.edu

This research report offers a framework for identifying emergent ideas about equivalence in beginning algebra students that is grounded in students' discourse. An exploration of the central question, "What are the conceptions that students have as they develop an understanding of equivalence?" is documented here. Latino students from six eighth grade classes were videotaped during group discussions and interviewed in pairs. Students' language on two tasks was used to develop and delineate a Reductive Model and an Equilibrium Model for equivalence.

The purpose of this study is to explore how students conceptualize equivalence as they move from arithmetic into algebra. National Council of Teachers of Mathematics (2000) calls for algebra throughout the K-12 curriculum and recommends that middle school students learn to generate equivalent expressions and solve linear equations. Equivalence is crucial for understanding algebraic expressions of quantitative relationships. Many state frameworks, such as the 1999 California Mathematics Framework (California Department of Education, 1999), call for every eighth grader to learn algebra, whereas previously most eighth grade algebra courses were designed with the highest achieving students in mind. There has been little research on algebra learning that shows how best to introduce formal algebra to younger students and specifically to a growing number of language minority students. This report discusses the first part of a larger study which links research and practice by investigating algebra classrooms as learning communities, student cognition in context, and how reform-based algebra curricula may have influenced students' understanding of equivalence.

## **Background**

This research is based upon sociocultural theories that emphasize discussion and collaboration, within a community in order to explain children's learning (Ernest, 1996; O'Connor, 1998; Wertsch, 1985). Wertsch restates a Vygotskian view of the social aspects of learning in terms of a transformation of mental functions through social interactions with more experienced members of a culture. This theoretical orientation led me to choose a study site where the classroom community engaged in social interactions that allowed negotiation, agreement and dissent to take place in order to develop shared meanings. These broad sociocultural theories reflect my experiences in the classroom with student learning. As students build up their own unique set of knowledge structures from pre-existing structures through social interactions, students learning in the same classroom typically display different levels of under-

standing of a concept. The first research question in this yearlong study explores the variations in students' understanding of equivalence. I chose to explore student cognition in a situation that used social interaction by listening to and analyzing students' discourse interactions during specific tasks on algebraic equivalence. My research question lends itself to a qualitative methodology formulated by Moschkovich and Brenner (2000) called a Naturalistic Paradigm that integrates complimentary methods for naturalistic and cognitive studies and uses a recursive process of analysis allowing the researcher to follow leads and assumptions from the data. In this methodology, multiple points of view are considered, theory generation and theory verification are interconnected, and the importance of studying cognition in context is emphasized. Moschkovich and Brenner (2000) state "A naturalistic paradigm provides a road map for understanding learners in their own terms and for highlighting the potential in what they know" (p. 461). Using a methodology that incorporates multiple points of view allows me to incorporate diversity of students in a positive way and avoid a deficit model of learning that has been previously found in research with minority students (Khisty, 1995; Moschkovich, 2000). Rather than focus on barriers to learning and student misconceptions, I wished to hear from the students how they think about equivalence in their own words. It is from students' natural language that the framework for equivalence emerges.

For this study, I will use Gattegno's (1974) distinction between identity, equality, and equivalence, where equivalence is the least restrictive relationship wherein replacements are possible. In equality, at least one attribute remains the same, and in identity all attributes are the same. Equivalence is a wider set that includes identity and equality and permits substitutions in transformations of equations. Although the use of an equal sign is a necessary part of relating two quantities in an equation, few studies have explored algebra students' understanding of equivalence. Studies in the late seventies and early eighties showed that young children understand the equal sign to be a "do something" signal (i.e., operational) rather than a symbol showing "the same as" (i.e., relational) (Baroody & Ginsburg, 1983; Behr, Erlwanger, & Nichols, 1976; Ginsburg, 1977). Kieran's study (1981) alluded to the possibility that large numbers of students in junior high, senior high, and college may take a simplistic view of equivalence. Kieran, in a short review of the research of equality from preschool through college, suggested that in the period of time between elementary school and high school, many students are confused about equivalence and hold a shaky grasp of the concept through high school. Kieran (1981) and Matz (1982) stress the particular importance of the transition period at approximately 13 years of age where students develop their concept of equivalence. Previous research suggests that equivalence is a stumbling block for students' success in algebra (Falkner, Levi, & Carpenter, 1999; Kieran, 1981; Matz, 1982; Steinberg, Sleeman, & Ktorza, 1990) and thus a strategically important area of research to pursue. Yet, in a review of the literature, scant research exists on how 13-year-olds think about equivalence.

I present a framework for students' conceptions of equivalence that was formed from an analysis of eighth grade student discourse during interview tasks. (See Figure 1.) There are two main types of equivalence that can be discussed in algebraic thinking: that of equivalence between expressions and that of equivalence between transformed equations. Pimm (1995) and Kieran and Chalouh (1993) discussed one aspect of algebraic thinking that takes place between successive lines of transformed equations. To simplify the framework for this report, only equivalence between transformed equations is related here.

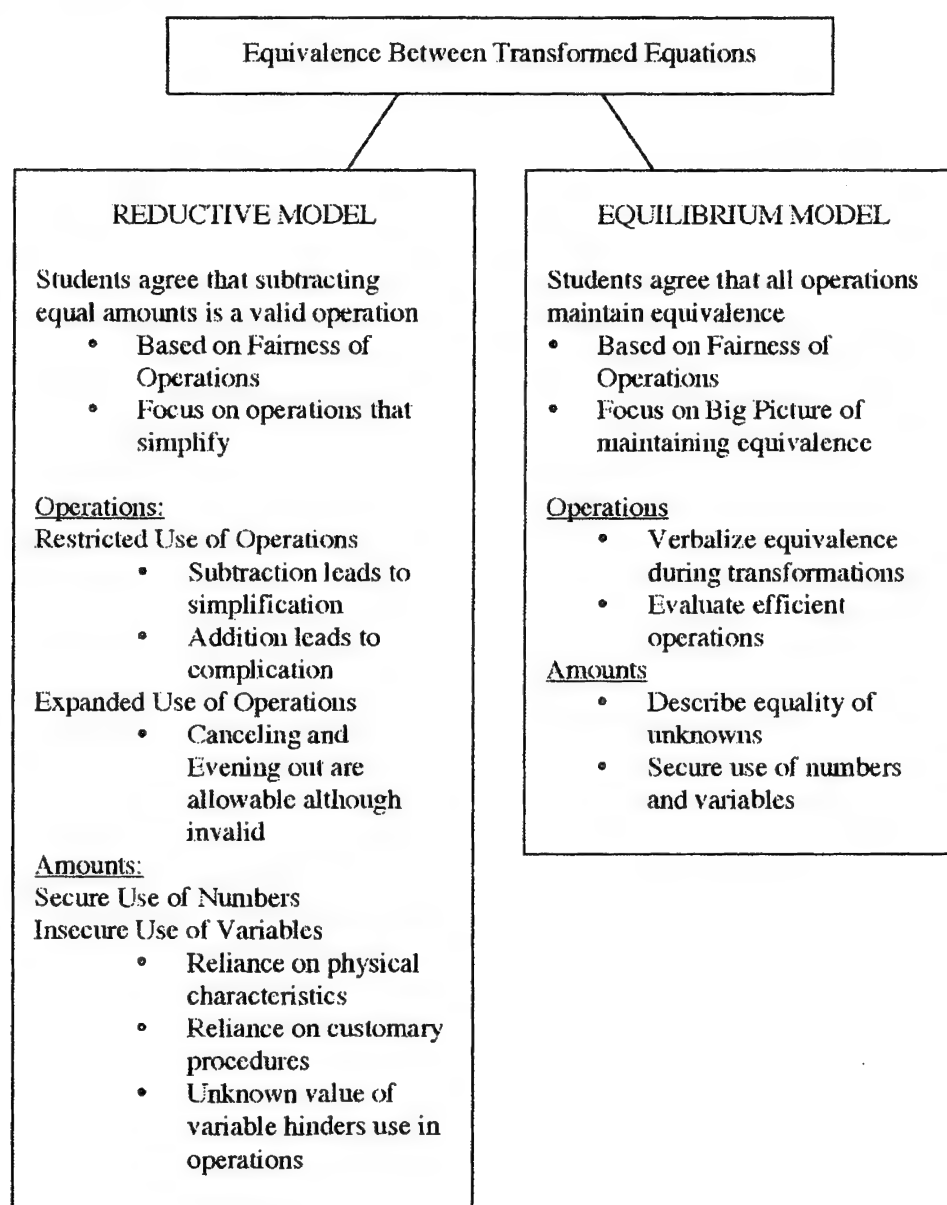

Figure 1. Framework for conceptions of algebraic equivalence in beginning algebra students.

Through student discourse, two major ways of thinking about equivalence emerged: what I call a Reductive Model and an Equilibrium Model for equivalence. In the Reductive Model, students fix their attention on subtracting equal amounts from both sides of an equation. Students focus on operations that reduce and simplify the equation and focus on the amounts being manipulated, not on the whole situation. In the Equilibrium Model, students conceive of equivalence as a balance where any operation that is applied evenly to both sides of the equation will maintain its equilibrium. In the Equilibrium Model students are focused, not on the amounts being manipulated, but on the maintenance of equivalence. I present data that support the models and further refine each after introducing the methods and two tasks used in student interviews.

### Methods

A case study design was used for this classroom-based research with a student pair as the unit of analysis. After a yearlong participant observation of six eighth grade classrooms in a predominantly Latino school district, 37 pairs of students participated in semi-structured interviews near the end of the school year. The students in the six classes were taught by one junior high school teacher using mathematics reform-based algebra curricula that have been widely used across the U.S. As the school district and the teacher from this large California junior high school were committed to algebra instruction for all eighth graders, the students in this study were typical, ranging from high-achieving to low-achieving students, with both Spanish-dominant and English-dominant language backgrounds. Group discussions that took place during introductory units on solving equations were videotaped. During the analysis of the group discussions, several questions about how students conceived of algebraic equivalence arose and four tasks were created that focused on these questions. The tasks in the paired interviews maintained the usual classroom practices of collaboration and negotiation and allowed me to closely examine student language and cognition in context and in a natural setting. Two of the tasks will be discussed in this report.

#### Task 1: The Money Task

The first task in the paired student interview pertained to a realistic, hands-on situation. Foreign currency, in the form of bank notes, large coins, and small coins, which lacked Hindu-Arabic numerals for familiar numerical references, were used as manipulatives in the Money Task. I told each student to imagine that they are in a foreign country and they are each purchasing an identical item. Each student gave me their bank note and I gave them change in the form of large and small coins. To one student I gave 3 large coins and 4 small coins in change. To the other student I gave 1 large coin and 18 small coins in change. After students agreed that the value of the money that each received back in change was the same, students were asked to work together to find how many small coins were the same as one large coin.

The interviewer probed for student thinking about equivalence by referring to what the student pair did with the coins and asking the pair to justify their solution. The Money Task did not involve symbolic manipulation and provided a concrete situation for students to justify their solution. Students' physical movements of the manipulatives were captured on videotape as they worked through the task.

### Task 2: Three Choices

The second task consisted of the initial steps in solving the linear equation  $6x = x + 7$  and comments by three fictitious students about the step  $-x = -x$ . The interview pairs were shown a piece of paper that read as follows:

Three students were shown the following set of equations and were asked: "What can you tell me about the  $-x = -x$  step?"

- |  |   |
|--|---|
| $6x = -x + 7$<br>$-x = -x$<br>$5x = 7$ | <ol style="list-style-type: none"> <li>1. The first student said, "You can't do that because you don't know what <math>x</math> is."</li> <li>2. The second student said, "You can sometimes do that, but not all the time. It depends on <math>x</math>."</li> <li>3. The third student said, "You can always do that, no matter what <math>x</math> is."</li> </ol> |
|--|---|

After student pairs selected the best response and discussed this problem, students were asked if the addition of unknowns was acceptable and the addition of unknowns with fractional coefficients was acceptable for certain equations.

The second task was designed to reveal what students perceive as acceptable steps for transforming equations. Several months before the interviews took place, all students had completed a four-week introductory unit on solving linear equations that included investigations into the addition and subtraction of unknowns.

### Data Sources

Data from the transcriptions of the interviews were mapped (i.e., significant episodes were charted along with actions and statements) to provide the key features of the task. By mapping each interview, analysis of key elements of an interview and the language used by student pairs was simplified. A constant comparative method of analysis (Glaser and Strauss, 1967) was used to analyze the videotape data in order to find the natural language used in student discussions about equivalence. Descriptive matrices using direct quote raw data and key phrases were used to aid analyses (Miles & Huberman, 1984).

## Results and Discussion

### Task 1 Result

#### Use of equals

Students created their own usage for the word *equal* and other terms by stretching their usage to novel verb forms and phrases. In addition to using the word *equal* as a verb comparing two amounts in an arithmetic expression, students began to use the word *equal* as an action verb that involves the evening up of two entities. The following examples illustrate this usage.

Using *equal* as a Comparison: “so that means these four coins are equal to this one” (Pair 30) and “which is equal to mine” (Pair 26)

Using *equal* as an Action Verb: “we can equal the value to this” (Pair 15); “two of these large coins should equal up to seven of these small ones” (Pair 24); “We still just have to equal them out” (Pair 4); “so that equals out” (Pair 3); “we are supposed to equal two of like the same thing” (Pair 18)

Students used *balance* and *cancel* in much the same way (e.g., “we can balance them out”) illustrating the transitional use of everyday language to describe algebraic processes. There was no standard way that students discussed algebraic equality, which may indicate that students created their own idiosyncratic forms to describe their actions for the interview tasks. Perhaps the new ways that students used the term *equal* shows transitional or novice entrance of the words into the mathematical register.

#### Patterns of use for terms of equivalence

Using a Naturalistic Paradigm, the researcher revisits the data with more focused questions and upon doing this, I found an interesting pattern. As I reconsidered the language of the student pairs who spoke of simplification using the terms *simple* or *less complicated*, I realized that most of these student pairs also described *taking away* in the same phrase. I looked specifically at the terms *take away*, *cancel*, *rid of*, *simple*, and *simpler*, and found a crossover of terms (i.e., students who used one term often used another of the terms *take away*, *cancel*, *rid of*, *simple*, or *simpler*). Originally, I had grouped the term *balance* with *cancel* and the other similar terms in my analysis, but I now saw that some student pairs used *balance* on its own without interchanging it with *take away*, *cancel*, *rid of*, *simple*, and *simpler*. I divided the students into groups that used the idea of simplification as its metaphor for equivalence and another group that used balance as the overarching metaphor for understanding equivalence. In the framework I characterized these two groups using the labels Reductive Model and Equilibrium Model.

**Task 2 Result**

Three general groups emerged from the responses of the second task, however, these groups do not respond to the three choices in the task. Table 1 illustrates the models students used for Task 2 based on the analysis of their language. The results appear to reinforce the findings from the first task.

**Table 1.** Two Models for Equivalence Used by Students in Task 2

| Reductive Model   |   | Equilibrium Model   |
|---|---|---|
| X Value Matters Group<br>(15 Pairs)   | Subtract Only Group<br>(7 Pairs)  | Always Group<br>(11 Pairs)  |
| Choice 1 or 2   | Choice 3  | Choice 3  |
| 1) Concern with amounts in equation   | 1) Hesitant to accept addition of unknowns  | 1) Explicit in describing value of variables  |
| 2) Concern with operations – simplification means subtract                    | 2) Prefer subtraction in order to simplify  | 2) Referred to Maintaining Equivalence in equations   |
| 3) Customary procedures determine acceptability of next step                  | 3) Used Whatever You Do Slogan  | 3) Used Whatever You Do Slogan  |
| 4) Physical shape of successive equations important                           | 4) Use invalid canceling operations   | 4) Evaluated step for efficiency  |
| 5) Call on higher authority rather than sense-making                          |   |   |
| Typical Responses for Each Group  |   |   |
| Pair 37: “You can’t take $x$ away because you don’t know what $x$ represents” | Pair 13: “So to find out what is $x$ we have to take away $x$ from here and from here so it can give you a number.” | Pair 2: “and are equal, so it doesn’t matter”   |
| Pair 10: “It has to depend on what $x$ will be”                               | Pair 15: “I think your supposed to take away a half.”   | Pair 9: “Since each is equal, you are allowed to take them away”                                    |
| Pair 18: “You need to solve for $x$ first and then get the answer “           | Pair 29: “So if we add one more $x$ , ... we’re not going to be able to find the $x$ at the bottom.”                | Pair 12: “Yeah, if it’s asking you to add it, because that’s what you’re trying to do, balance it.” |

*Note.* Four student pairs whose problems with coefficients made it difficult to determine conceptions of equivalence are not included in the table.

**Reductive model- Excerpt 1**

The most interesting results from Task 2 were the seven student pairs in the Subtract Only Group, who answered “You can always do that, no matter what  $x$  is,” (Choice 3) but when questioned about an addition of  $x$  step (i.e.,  $+x = +x$ ) to both sides of an equation, student pairs rejected the addition step. The following interview excerpt from students A and J of Pair 23 illustrates a typical interchange between students in the Subtract Only Group and the interviewer.

1. A: because whatever you do to one side you have to do to the other.
  2. Interviewer: Can you do that? [Can you add half an  $x$ ?]
  3. J: I don't think so, aren't you supposed to subtract all the time?
  4. A: I think that you couldn't do that - you need to subtract it
- [Later on in the interview, the students do a problem together with the interviewer that included an addition step. The transcript picks up from there.]
5. Interviewer: What about this step? You were thinking that you can only subtract, but we added.
  6. J: Maybe you can add... [laughs]
  7. Interviewer: Maybe!
  8. J: It kinda seems wrong. We're used to subtracting it from both sides

Excerpt 1 captures the students' realization that their scheme for simplification may be widened to include operations other than subtraction (line 6). The students' explain that the customary procedure for solving equations is a routine that involves subtraction (lines 3 and 8). Although they stated, “whatever you do to one side, you do to the other,” it was difficult for students to recognize operations other than subtraction were permissible. Six of the seven student pairs in this group used the *Whatever You Do* Slogan to justify the subtraction of  $x$ , but then decided that the addition of a variable did not hold under the rule that they had just stated.

**Reductive model-Excerpt 2**

The next excerpt with Student D of Pair 35 shows the unease that students in the  $X$  Value Matters Group felt when approached with the idea of adding unknowns. After asking the students in Pair 35 whether it is possible to add one half  $x$  to both sides of the equation, the students respond and illustrate in the transcription below that addition will not aid in simplifying an equation and finding a solution.

1. D: I don't think you can because they are both positive and that would just increase ... Increase it
2. Interviewer: And what's wrong with increasing it, tell me?
3. D: You have to find the value of  $x$

4. Interviewer: And if you keep increasing it?
5. D: You won't find it.

Excerpt 2 shows a student verbalizing the idea that subtraction is the best way to simplify an equation and find the value of  $x$ ; adding an unknown will complicate the equation and make it impossible to find the solution for  $x$ . The students in the X Value Matters Group did not readily see that operating with the variable  $x$  leads to “figuring out what  $x$  equals.” The key issue in these students’ explanations was the overriding concern to find the value of  $x$  and the indifference towards the steps leading to the solution. By focusing on the endpoint, customary procedures for solving, and the narrowing shape of the equation set, the students neglected the process of transformation and ignored equivalence.

### **Whatever you do slogan**

I have termed the common phrase, “Whatever you do to one side, you do to the other” the *Whatever You Do Slogan*. I use the term *slogan* because it describes a catchy phrase whose meaning may vary from person to person, and thus, is ripe for misinterpretation. Because the terms *whatever* and *do* are vague, students developed their own meaning for the terms, and for some students in the Reductive Model the slogan came to mean: *use only subtraction in order to simplify*. For two student pairs in the Reductive Model, the slogan meant “cancel out” on both sides by adding a positive  $x$  to one side and a negative  $x$  to the other. For students using the Equilibrium Model, the slogan enabled them to use all operations and apply them commensurately to both sides of an equation. For 26 of 37 student pairs who used the slogan in the interviews, I learned to probe deeper in order to uncover the students’ specific meaning behind the phrase.

### **Operational fairness**

One constant and robust theme emerged from the data—that of students’ ideas of fairness applied to operations. Students were often adamant about applying equal operations to both sides of equations and used ideas of fairness to justify equal operations. Out of the 37 interviews on each task, I saw only two cases where student pairs agreed that unequal operations were valid operations. Operational fairness is the firm belief that applying equal operations of equal amounts to both sides of an equation is a fair and valid operation. I make a distinction between agreeing that an operation is valid and realizing that a new equivalent equation has been created which continues to maintain equivalence to the original equation.

### **Reductive model overview**

From the Money Task, a pattern emerged that showed two models for equivalence; one group that used balance and one that used equal subtractions as the means to simplification. With the use of concrete manipulatives in the Money Task, I wondered

whether the task itself was influencing students to join the ideas of simplification and subtraction, however, the responses in the Second Task, which included both addition and subtraction operations of unknowns, also showed this pairing up of simplification and subtraction. The responses from the Second Task appeared to support the two models that emerged from the Money Task and led to a further refining of the models. In the Second Task, the Subtract Only Group was hesitant to accept addition of variables and preferred subtraction as the means to simplify. Students in this group had a restricted view of the operations that are used in transforming equations. Two student pairs in this group expanded their use of operations to include an invalid canceling step in order to simplify the equation. The *X Value Matters* Group was insecure in their use of variables although secure in their use of numbers in transforming equations. The student pairs in this group relied on physical characteristics and customary procedures in solving equations and did not tend to focus on overall goal of maintaining equivalence.

### **Equilibrium model overview**

The results of both tasks appeared to show that some eighth grade students conceive of equivalence using a balance in equilibrium model that is based on principles of fair operations and is focused on the maintenance of equivalence as equations are transformed. Student pairs in the Always Group explicitly described the equality of the value of the unknowns and extended the idea of equivalence to variables. Most students also verbalized the maintenance of equivalence between equations during transformation and then evaluated the operations for efficiency. For example, Student Pair 17 suggested that a step was possible, but not productive when they stated, "I think you could, but why would you want to add half  $x$  because it would make it more complicated." As in this example, student language helped to refine the Equilibrium Model. The results of the second task, which used symbolic manipulation, helped to verify and delineate the characteristics of an Equilibrium Model that emerged in the first task, which provided a concrete manipulative situation without the use of variables.

### **Conclusion**

This study reports that students express their ideas of equivalence in various and original ways and it is this language that grounds the framework for algebraic equivalence. Two models for eighth graders' conceptions of equivalence are documented: a Reductive Model in which students readily agree that subtraction operations are valid and where students focus on the amounts used in the operations; and an Equilibrium Model in which students agree that all operations maintain equivalence and where students focus on the overall maintenance of equivalence in transformed equations. Results from two interview tasks with 37 pairs of Latino eighth graders supports the emergence of two models for identifying ideas about equivalence in beginning algebra

students. If students are to develop their ideas of equivalence by sharing meanings via discussions and interchange, then it is important that the curricular models and the vocabulary in the curricular models that are introduced to eighth grade students enable them to communicate their ideas to others and move them toward a better understanding of equivalence.

The goal of equity is embedded in mathematics reform curricula, and therefore it is important and imperative that the research community link research and practice in order to investigate how best to introduce algebra to young learners so that all students can succeed. This report is the first of a series of investigations designed to support Latino students in the learning of algebra by exploring how curricula influence students' understanding of equivalence and whether language minority students are benefiting equally from reform-based curricula.

The 3UV (3 uses of variable) model involves a detailed decomposition of variable in its three main uses in elementary algebra: specific unknown, general number and related variables. This model is used as a guide to design teaching materials and a teaching strategy for elementary algebra through the differentiation and integration of the different uses of variable. Activities for an introductory elementary algebra course were developed and used with ten 12 to 13 years old students who were just being introduced in their approach to elementary algebra. We present the results obtained after 15 teaching sessions in which students worked following a spiral path of differentiation and integration of the different uses of variable. The results show, on the one hand, the appropriateness of the 3UV model for the design of teaching materials and of the teaching strategy. On the other hand, we show evidence of the possibility to introduce students to different uses of variable emphasizing their differentiation and integration. The capability of students to shift between the different uses of variable is illustrated by an excerpt of a group discussion.

### Introduction

Several researchers state that the development of algebraic knowledge implies a solid understanding of the concept of variable (Bills, 2001; Philipp, 1992; Ursini & Trigueros, 2001; Warren, 1999). Supporting this view we consider that more emphasis should be made to help students develop an understanding of this multifaceted concept as a global entity. From our point of view students should be taught explicitly to differentiate between the different uses of variable and to integrate them in a single conceptual entity: the variable. In previous studies the basic capabilities underlying an understanding of variable have been summarized (Ursini & Trigueros, 2001). An elementary understanding of variable was described in terms of the following basic capabilities:

- to perform simple calculations and operations with literal symbols;
- to develop a comprehension of why these operations work;
- to foresee the consequences of using variables;
- to distinguish between the different uses of variable;
- to shift between the different uses of variable in a flexible way;
- to integrate the different uses of variable as facets of the same mathematical object.

Moreover, a theoretical framework, the three uses of variable model (3UV model), has been proposed as a basis to teach the concept of variable (Ursini & Trigueros, 2001). The 3UV model considers the three uses of variable that appear more frequently in elementary algebra: specific unknown, general number and variables in functional relationship. For each one of these uses of variable, the 3UV model stresses different aspects corresponding to different levels of abstraction at which it can be handled. The requirements for an elementary understanding of variable can be presented in a schematic way as follows:

The understanding of *variable as unknown* requires to:

- U1. recognize and identify in a problem situation the presence of something unknown that can be determined by considering the restrictions of the problem;
- U2. interpret the symbols that appear in equation, as representing specific values;
- U3. substitute to the variable the value or values that make the equation a true statement;
- U4. determine the unknown quantity that appears in equations or problems by performing the required algebraic and/or arithmetic operations;
- U5. symbolize the unknown quantities identified in a specific situation and use them to pose equations.

The understanding of *variable as a general number* implies to be able to:

- G1. recognize patterns, perceive rules and methods in sequences and in families of problems;
- G2. interpret a symbol as representing a general, indeterminate entity that can assume any value;
- G3. deduce general rules and general methods in sequences and families of problems;
- G4. manipulate (simplify, develop) the symbolic variable;
- G5. symbolize general statements, rules or methods;

The understanding of *variables in functional relationships* (related variables) implies to be able to:

- F1. recognize the correspondence between related variables independently of the representation used (tables, graphs, verbal problems, analytic expressions);
- F2. determine the values of the dependent variable given the value of the independent one;

- F3. determine the values of the independent variable given the value of the dependent one;
- F4. recognize the joint variation of the variables involved in a relation independently of the representation used (tables, graphs, analytic expressions);
- F5. determine the interval of variation of one variable given the interval of variation of the other one;
- F6. symbolize a functional relationship based on the analysis of the data of a problem.

An understanding of variable implies the comprehension of all these aspects and the possibility to relate both, the aspects and the uses of variable in different problems. This implies developing the ability to *interpret* the variable in different ways depending on the specific problematic situation, acquiring in this way the flexibility in shifting between its different uses and the capability of integrating them as facets of the same mathematical object. It is necessary as well to develop the ability to *manipulate* symbolic variables in order to perform simple calculations. Both these abilities help students to develop a comprehension of why the operations work. The ability to *symbolize* rules and relationships in different problem situations leads to foresee the consequences of using variables. Starting algebra students should develop gradually these basic capabilities that are related to a deep understanding of elementary algebra.

Based on the 3UV model an approach to the teaching of algebra following a spiral path of differentiation and integration of the different uses and aspects of variable presented above has been suggested (Trigueros & Ursini, 2001). At each level of complexity all the three uses of variable are studied following a two phases pattern of instruction: first, situation are presented where the three uses of variable are introduced in a differentiated way; then students are faced with situations where it is necessary to integrate the three different uses of variable just studied.

In this paper we present an example of teaching materials for an introductory elementary algebra course, developed following the 3UV model and the suggested spiral path for teaching. We analyze 12-13 years old students' capability to differentiate between the different uses of variable when working with the proposed tasks. The teacher's knowledge about the concept of variable and of the 3UV model, her ability to conduct the activities, to interact with students and to generate enriching discussions are in the core of the success of the teaching strategy.

### Methodology

Several activities of different levels of abstraction were designed in terms of the 3UV model. They were organized in three blocks. The first two blocks have the same structure: first there are a series of activities in which the different uses of variable are

considered in a differentiated way; after that an activity involving the three uses of variable is presented. The third block originally contained only activities involving the three uses of variable, but it was slightly modified during the experiment. The following is a brief description of the content of each one of the three blocks:

*Block 1.* There are 12 activities in this block, all of them concerning numeric patterns. The first seven activities require working with general numbers. Through analyzing numeric patterns students are expected to approach the aspects G1, G2, G3 and G5. The same numeric patterns are after that used in the following two activities in order to work with specific unknowns. The aspects U1, U2 and U4 are involved. The activities 10 and 11 use as well numeric patterns as support, but students' attention is directed towards functional relationships. They are expected to approach F1, F2, F3, F4 and F5. The last activity requires working with the three uses of variable and the aspects involved are G1, G2, U1, U2, F1 and F4.

*Block 2.* Eleven activities integrate this block. All of them include areas of geometric figures. In the first five activities general numbers through the aspects G1, G2, G3 and G5 are present. The following four activities emphasize the aspects U1, U2, U4 and U5 of the specific unknown. The activity 10 involves variables in functional relationship with F1, F2, F3, F4, F5 and F6. As in block 1, the last activity requires working with the three uses of variable. The aspects involved are G1, G2, U1, U2, F1 and F4.

*Block 3.* In this block there are 7 activities. The first 3 activities involve related variables with F1, F2, F3, F4 and F5. These activities were added to the original design in order to equilibrate students' experience with the three uses of variable. In fact, during the first two blocks there were more activities with general numbers and specific unknowns than with variables in functional relationship. All the subsequent 4 activities require working with the three uses of variable and with all the aspects students worked with during blocks 1 and 2.

This organization of the activities aimed at following the spiral path suggested by the 3UV model for teaching.

A group of 10 students, aged 12 - 13 years old, attending the first grade of a public secondary school in Mexico, worked with these activities during 16 sessions. The 10 children were part of a larger group, but they were selected by their mathematics' teacher to attend the 16 sessions during the mathematics' regular hour. The researcher acted as the teacher of the 10 students' group. She presented the activities to the whole group and these were solved through a common discussion. She directed the group discussion by posing questions promoting the participation of all the 10 students in oral and/or written form. During the discussion a paper-board was used instead of a blackboard and students were invited to step forward and to write on it. Additionally they were asked to answer the posed questions individually on a paper sheet. All the

sessions were videotaped, the paper-board pages and all the students' written productions were kept in order to be analyzed. At the end of the 16 sessions three students were interviewed in order to obtain more information about some of their written productions. Three researchers independently of each other analyzed the data. Their results were summarized, exchanged and negotiated until reaching a consensus. This method was used to validate the interpretation of the data.

### Results

In order to present the results obtained we will discuss in detail the outcomes of the 16<sup>th</sup> session in which activity 5 of block 3 was developed. This activity requires working with the three uses of variable and with the aspects G1, G2, G3, G5, F1, F2, F3, F6, U1, U2, U4 and U5. Our purpose during this session was twofold: on the one hand we wanted to observe if the experience acquired during the previous activities pupils were able to shift between the different uses of variable approaching the different aspects; on the other hand we wanted to detect the possible difficulties in doing this.

A table describing the equivalence between pesos and dollars for 5, 8, 20, 35, and 100 dollars was presented. The column on the left represented the quantity of dollars and the one on the right its equivalence in Mexican pesos. The exchange rate used was 9.5 pesos per dollar. The teacher asked *What is this table about?* in order to introduce the activity and focus students' attention. The following dialog followed the introductory stages:

T (Teacher): What information can we get from this table?

In this way the teacher introduces the activity and calls pupils' attention on the data presented in the table.

M (Marcela): From dollars to pesos?

K (Karla): How much does it cost a given quantity of dollars.

M: How much do 5 dollars cost. (pointing with her pen to the table displayed on the paper-board)

T: Yes, how much do 5, 8, 20 dollars cost, any quantity of dollars. In that table, what quantities are we relating?

M: From dollars to pesos?

T: Although in this column it says "dollars", what are we actually representing here?

M: How many dollars.

T: How many dollars, that is the number of dollars. And in this one? (pointing to the other column)

K: The value of the dollars.

M: Yes, in this column we put the value of the dollars.

K: The equivalence from dollars to pesos. (moving her hand to indicate that she is going from one column to the other)

During this initial verbal interchange we can observe that Marcela and Karla immediately recognize that the quantities presented in the table are correlated. Karla stresses it using the word “equivalence” and Marcela by saying “from dollars to pesos” (F1). We can also see the teacher helping them to make explicit the quantities involved in the correspondence. The teacher comments help them to make their statements in a more precise form.

T: The equivalence from dollars to pesos. Then, in this table we are relating the number of dollars with the number of pesos. Marcela come to the board, please, now, what operation do we have to do to know how many pesos correspond to five dollars? And write the operation here. (showing the corresponding part on the table)

M: I have to multiply. Do I?

T: Yes, but, what is it that do you have to multiply?

M: ....

T: Yes, for example, if you want to know how many pesos correspond to five dollars.

K: 9.5 by 5.

T: Do you agree Marcela? (Marcela agrees by moving her head) Do it on the board (Marcela does the product using vertical notation on the board)

T: Then, what is the operation you do if you want to know how many pesos correspond to five dollars?

M: By five.

T: But what did you multiply? Write the operation in horizontal notation, here on the board. (pointing to a space on the board to the right of 47.5 Marcela writes  $9.5 \times 5$ )

T: 9.5 by 5, well, what does the 9.5 represent?

M: the equivalence of 5 dollars.

Everybody: Noooo!

K: A dollar costs 9.5, a dollar is equivalent to 9.5 pesos.

T: Very well, and what does the 5 represent?

M: The number of dollars.

T: The number of dollars. Now, what do we have to do to know how many pesos are equivalent to 8 dollars?

M: Multiply by 9.50. (Marcela writes 9.50 to the right of 76. Marcela goes back to her place)

T: And what do we have to do to know how many pesos are equivalent to 35 dollars? Sandy?

S. (Sandy): 9.50 by 35.

In this passage the teacher wants to call the attention of the students about the rule that relates both columns of the table. She does it starting from particular cases and posing questions in a way that can help to fix the attention of the students in the mathematical form of the correspondence. In the group discussion more students intervene. From the responses given by Karla, Marcela and Sandy, we can observe that the students are capable of recognizing the appropriate method to determine the number of pesos that correspond to a given number of dollars (G1, F1), and also that they are able to state explicitly the operation needed to determine the number of pesos when the number of dollars is given (U4). We can see here that during the group discussion, the possibility of listening to different voices helps the members of the group to structure their thinking in a more formal way. This can be seen, for example when Marcela, who has difficulties in expressing verbally her point of view, is helped by the clear and precise interventions of Karla to formalize her reasoning.

T: Yes, and here what does the 9.50 represent?

S: The value of one dollar.

T: And the 35?

S: It is the number of dollars.

T: Well. We have seen that to determine the number of pesos that correspond to a given number of dollars, we have to multiply the number of dollars by the value of one dollar. Also, when we first looked at this table, what values did we say that we can write in this column? (pointing to the dollars column and inviting Jorge to come to the board)

The teacher summarizes, once more, the ideas that the students have just expressed, in order to generalize the procedure they have deduced taking as a starting point the previous examples. The teachers also introduces the idea of general number. By doing this she helps them to start the symbolization part of the activity.

J (Jorge): The value that we want.

T: Any value, and what symbol can we use to represent that value in general?

J: A letter.

T: A letter, which one would you use? Write it down on the table on the board (pointing one of the empty rows. J writes the letter h on the board)

T: Very well, and what does that h represents?

J: It represents any number.

T: And in this particular case, what does the h represent?

J: The number of dollars.

In this dialogue it is clearly shown that this student is capable of thinking about a general number as representing any value (G2), and that he feels the necessity of using a symbol to represent it, more specifically, a letter (G5). While he does this, the group follows attentively the discussion and assert when the letter h is chosen to symbolize the general number. These students are thus capable of symbolizing a general number by using any letter, h in this case, and they recognize in that letter a symbolic variable. They are not limited to using specific letters traditionally used by teachers and books as x or y. Another aspect that seems important to us is their capability to interpret the variable as the number of dollars and not as a label or abbreviation of the word dollars. The teacher's role in this dialog is as a guide to call the students' attention on the use of symbols to represent general numbers, and to make sure that the interpretation they do of the symbol is understood by the whole class.

T: Very well. And of we want to know how many pesos correspond to that number of dollars, what operation do we have t do?

J: We need the number of pesos, so that when I do a division I get the number of dollars.

T: Let's see again, what operation do we have to do to know the number of pesos that correspond to a number of dollars?

J: ah! Multiply.

T: What do you multiply? (Jorge writes on the board  $h \times 9.50 = 530$ )

The questions posed by the teacher are oriented to help the students verbalize the general rule and to verify if Jorge can write  $h \times 9.5$  as a general expression (G5) that represents the number of pesos. However, as can be noted, Jorge writes instead an equation (U5), where h has the role of an unknown number. This suggests that he has difficulties in symbolizing a general rule (G5) and that he needs to interpret h as an unknown (U2) to make sense of the question.

T: Well, but if I multiply the number h of dollars by 9.50 what is the result of that operation?

S: Any number.

T: Yes, any number, we don't know which one. Then, how do we write that? (J: write  $h \times 9.50 = z$ )

T: The result is another number that we have represented in this case, with a z.

T: How do we obtain the value of z?

V (Vanessa): The values of z is the result of a multiplication, and we represent it with a letter because we don't know its value yet. It is an unknown number.

The teacher goes back to the previous question trying to see if the students can generate the expression  $h \times 9.5$  (G5), and can interpret it as a general number which in this particular case represents the number of pesos. The students, however, do not produce the expected expression and in order to make sense of the operation on h they generate a functional relationship (F6). Jorge, who is still standing in front of the board, writes  $h \times 9.5 = 530$ . From students' interventions we can also observe that they are interpreting the letter z as capable of taking any value, that is, letter z is interpreted as a general number (G2), but they are recognizing as well that its value depends on the given restriction  $h \times 9.5$ , that is, that they are recognizing the correspondence (F1).

T: Very well, Jorge wrote  $h \times 9.50 = 530$ , what is the value of z in this case?

V: It is 530.

T: Well. In this equation what is the value of h?

V: 530 divided by 9.5.

The teacher uses the expression previously written by Jorge to work on the aspects related to variable as specific unknown. From the dialog it can be observed that Vanessa recognizes that h is an unknown number that can be determined (U1), and she is able to indicate the operation needed to determine it (U4). During all this process, it can be seen how the students are shifting from one use of the variable to another without any difficulty. Observe as well how the teacher is coordinating the discussion following the path traced by the students' interventions.

T: Then, what is the value of h?

M: Any value.

Everybody: Noooo!

K: No, because the value of h depends on z and we already have z.

T: Well, because the value of h depends on a result that is already known, in this case it is 530, here. Then how many values can h take?

Everybody: One!

It is clear here that the students recognize that in this expression, an equation, the variable can take only one specific value (U2); and that this is due to the restrictions of the problem, in this case the value that has been given to  $z$ . Karla's answer shows that she is recognizing the correspondence between the variables  $h$  and  $z$ , that is, that the value of one of them depends on the value assumed by the other, and that for a given value of  $z$  there is a corresponding value for  $h$  (F1). Here again, the role of the group discussion and of the different interventions in guiding the reasoning process of the students, and in the way the teacher formalizes their findings, can be observed.

T: Only one and, what is that value?

Several students: It is 55.

The students determined the value of  $h$  doing the necessary arithmetic operations. This means that they could find the value of the independent variable  $h$  when the value of the dependent variable  $z$  was given (F2). At the same time, they were able to determine the value of the unknown considering the equation  $h \times 9.5 = 530$  (U4).

T: And if the value of  $h$  is 50, what is the equation that represents this situation?

J: It is represented like this... (he writes  $50 \times 9.5 = n$ )

T: And why  $n$ ?

J: Because we don't know yet what is the result of  $50 \times 9.5$ .

T: And if instead of writing  $50 \times 9.5 = n$ , we write  $50 \times 9.5 = z$ , are we changing the sense of what we are trying to say?

A (Alejandra): No it is the same. Because what is changing is the letter we are using to represent the variable, and the variable can have the same value even when it is represented using different letters.

In this part of the dialogue we can observe that Jorge does not have any difficulty to substitute the given value to  $h$  (F2). While doing this, however, he changes the representation of the dependent variable. This shows his ability to represent a specific unknown using any letter but, at the same time, puts forward the necessity to call students' attention on equivalent expressions. This propitiates a new question by the teacher in terms of the equivalence of the different written expressions. It is worth noting the clarity of the concise explanation given by Alejandra, which shows that she really understands the use of the variable. The teacher is also guiding the students in their understanding of the symbolization of the general rule by means of a functional relationship.

T: Well, in the expression  $50 \times 9.5 = n$ , how many values can  $n$  take?

J: Any value.

Everybody: Nooo!

T: Why?

F (Fabiola): Because its value becomes dependent of 50.

T: Why?

F: It is dependent on h, but as we already know the value for h, which is 50, now n or z are depending on 50. Now n and z have to be the same as the result of multiplying  $50 \times 9.5$ .

T: Then the expressions  $50 \times 9.5 = n$  and  $50 \times 9.5$  are equivalent?

Everybody: Yes!

T: Now what is the value of n or z?

F: It is 475.

In this last part of the discussion it can be seen that the whole group agrees with Alejandra's comment. Fabiola, for example emphasizes that the letter used to represent the variable is not important, and the whole group recognizes the equivalence between the two expressions. Here again it is shown that students are able to recognize that in an equation the variable can assume only one value (U2). They are capable of determining the value of the specific unknown that appears in an equation (U4). In doing this in the given example, they show as well their capability to determine the value of the dependent variable when the value of the independent variable is given (F3).

The analysis of students' interventions and productions show that after 15 sessions they had acquired the capability to recognize the different uses of variable and they could use them when working with simple algebraic problems. They were able to differentiate them and also to integrate them to solve specific problems during the global solution process. They showed a capability to shift between the different uses of variable in a flexible way. The excerpts we presented above show that students could approach the great majority of the different aspects involved in the given problem situation. There is evidence showing their capability to perceive rules (G1) and to deduce general rules (G3); to interpret a symbol as representing a general number (G2) and to differentiate it from the same symbol representing a specific unknown (U2). They could recognize the presence of a specific unknown (U1) and determine its value when it appeared in an equation by performing the required arithmetic operations (U4). Students recognized the correspondence between related variables (F1), and they could determine the value of the dependent variable given the value of the independent one (F2) or determine the value of the independent variable given the value of the dependent one (F3). They could as well express symbolically a functional relationship (F6) and write an equation (U5). However, some difficulties were detected as well. Students could not symbolize a general rule (G5) they had already recognized, although they were able to apply it to solve particular cases.

During this process the teacher's interventions were very important for guiding students' work and for calling their attention on the different uses of variable and the related aspects. Observe that all her interventions consisted in rephrasing students' answers to her questions and in posing new questions. This approach led to the participation of the whole group and to a common discussion of the ideas students were externalizing. On several occasions she asked students to make explicit the meaning of the literal symbols they were using. This helped them get aware of the role played by the variables in the different moments of the solution of the problem. Moreover, in spite of her schedule she was sensible to students' understanding and this led to a real dialog between students and with the teacher that led them to become completely involved in the proposed task.

### Conclusions

This research shows that using the 3UV model as a basis for the design of a teaching strategy is feasible. The teaching approach followed a spiral path of differentiation and integration of the different uses and aspects of variable. In each block of activities students worked with all the three uses of variable following a two phases pattern of instruction: first, situation were presented where the three uses of variable were introduced in a differentiated way; then students were faced with situations where it was necessary to integrate the three different uses of variable just studied. The results obtained show that it is possible to introduce students to the study of the different uses of variable and work with its different aspects since their first courses of algebra. The episode shown in this paper makes it possible to appreciate students' strengths and weakness when they work with variables. The process of understanding the different uses of variables takes time. Some integrations and differentiations that have to be made are of a grater complexity than others. This implies that in some cases more attention has to be paid to the development of some notions. An example shown here is the difficulty students have to recognize an open expression as a conceptual unit, and not only as the result of the operation on a general number.

We want to stress that in an approach like this one, the role played by the teacher is fundamental. It is her responsibility to determine the degree of difficulty of the activities done in class, and to find a way to give enough opportunities to students to interpret, manipulate and symbolize the different uses of variables. She has also to be able to diagnose students' capabilities and difficulties during their interventions and to turn them into opportunities of conceptual growth in their learning of algebra. We want to stress as well, the fundamental role played by the explicit and implicit intervention of the group during discussions. Although these interventions can deviate the learning trajectory originally intended by the teacher into new directions, they become significant in the process of the students' understanding.

## DECONTEXTUALIZED RATIOS IN MIDDLE-SCHOOL STUDENTS' SOLUTIONS TO AN ASSOCIATED-SETS PROPORTION PROBLEM

Matthew R. Clark  
North Carolina State University  
mrclark@unity.ncsu.edu

Sarah B. Berenson  
North Carolina State University  
berenson@unity.ncsu.edu

After noticing students' lack of success using fractional representations of ratios to solve an associated-sets proportion problem, we hypothesized that middle-school students who are successful at solving missing-value problems may not attach contextual meaning to fractional representations of ratios when necessary to solve other types of proportion-related problems. In our first step to gather evidence, we conducted a quantitative study and found significant associations between students' notation (fractional versus non-fractional) and whether students maintained the context of the problem in their solution, between students' notation and score on the problem, and for the students who used fractional representations, between students' score and whether they maintained the context of the problem in their solution.

### Introduction

An understanding of proportion—the equivalence of two ratios—depends on a sufficient prerequisite understanding of ratio. According to Sowder et al. (1998), an understanding of ratio is essential to the transition from additive to multiplicative thinking; however, the topic of ratio receives little attention in elementary-school classrooms, and when it is covered the treatment often lacks depth (Post, Cramer, Behr, Lesh, & Harel, 1993).

While working on a larger study about how teachers understand and how textbooks present the relationship between ratios and fractions, we asked the following: Is there an association between students' notation for ratios—in particular, fractional versus non-fractional—and their success solving problems?

### Conceptual Framework

We define proportional reasoning from the perspective of a relationship between two variables that describe a linear function (Karplus, Pulos, & Stage, 1983). The emergent perspective (Cobb & Yackel, 1996) is an appropriate lens for this investigation because of the conjectured reflexive relationship between classroom mathematical practices and individuals' mathematical conceptions and activity. For proportion-related problems, strategies and notation shown by teachers and in textbooks are adopted by many students who fail to connect them to their understanding of ratios and fractions and therefore have no conceptual foundation for using them in a meaningful way (Clark, Berenson, & Cavey, in review). The students who participated in this study attended 25 different middle schools; therefore, no single teacher or classroom environment had an impact on the results.

## Methodology

### Data Sources

We analyzed the written responses of 137 students to an associated-sets problem (Lamon, 1993), “the pizza problem,” which is as follows: *There are 7 girls with 3 pizzas and 3 boys with 1 pizza. Who gets more pizza, the girls or the boys?* Responses were scored according to Allain’s (2000) four-point rubric: 4 points for appropriate strategy and correct answer, 3 points for appropriate strategy but incorrect answer due to a computational error, 2 points for correct answer but no demonstration of strategy, and 1 point for inappropriate strategy and incorrect answer.

### Coding Schemes

We coded the students’ solutions to the pizza problem according to two dichotomous variables: *notation*, either fractional or non-fractional, and *context*, whether the student maintained the context of the problem in her solution by using labels or diagrams for the elements of the problem, such as boys, girls, pizzas, and slices of pizza (if she divided them). We also used another problem that we refer to as “the coffee problem,” a standard missing-value problem, to narrow our sample for some statistical tests because we wanted to identify a subgroup of students who were successful at answering a missing-value problem. We used the coffee problem to separate the students into two groups—the 86 students (63%) who received a perfect score and the 51 students (37%) who did not.

### Statistical Analysis

For statistical tests, we used SAS software and the Pearson chi-square test for association between notation and context and a cumulative logit model for multinomial ordinal data to compare groups’ scores.

## Results and Discussion

On the pizza problem, the students who used non-fractional notation were more likely than those who used fractional notation to maintain the context of the problem in their solution (see Table 1).

The Pearson chi-square value of 7.92 ( $p < .01$ ) is sufficient to reject the null hypothesis of no association and would have been larger if we could have confirmed

**Table 1.** Frequency Counts for the Pizza Problem (N=137)

| Notation       | Context | No context |
|----------------|---------|------------|
| Fractional     | 34      | 40         |
| Non-fractional | 44      | 19         |

in interviews that some of the 19 whose solution was coded as non-fractional and no context simply guessed without working the problem and we therefore could have deleted them from this analysis.

While analyzing notation and context in the students' work, we began using the term *decontextualized ratio* to refer to students' written representations of ratios that were detached from the meaning of the problem. For example, a common error on the pizza problem was writing the relationships between the associated sets as  $7/3$  and  $3/1$  without any reference to what the numerators, denominators, or fractions stood for and to conclude that because  $3/1$  is the larger number that each boy got more pizza than each girl.

Of the 86 students who received a score of 4 on the coffee problem, those who used non-fractional notation on the pizza problem scored better than those who used fractional notation (see Table 2). The notation variable is significant ( $p < .01$ ) in explaining the difference in scores.

Of the students in this subgroup who used fractional notation on the pizza problem, those who provided context in their solution scored better than those who did not (see Table 3). The context variable is significant ( $p < .01$ ) in explaining the difference in scores.

### Note

Data for this study was collected at a program supported by the National Science Foundation under Grant No. 9813902. The opinions expressed in this report are those of the authors and do not necessarily reflect the views of anyone at NSF.

**Table 2.** Frequency Counts for Notation and Score (N=86)

| Notation       | 4  | 3 | 2  | 1  |
|----------------|----|---|----|----|
| Fractional     | 25 | 2 | 14 | 16 |
| Non-fractional | 22 | 1 | 3  | 3  |

**Table 3.** Frequency Counts for Context and Score for Students Using Fractional Notation (N=57)

|            | 4  | 3 | 2 | 1  |
|------------|----|---|---|----|
| Context    | 17 | 0 | 6 | 5  |
| No context | 8  | 2 | 8 | 11 |

## HOW 4-6 GRADE STUDENTS IDENTIFY ALGEBRAIC PROBLEMS THAT ARE ALIKE AND RANK THEM BY DIFFICULTY

Galina Dobrynina  
Wheelock College  
gdobrynina@wheelock.edu

Problem setting has been researched as a factor that influences students' perception of problem likeness as well as success in solving problems (Krutetskii, 1976; Schoenfeld, 1985; Silver, 1981). The majority of these studies were conducted with high school or college students. Researchers discovered that expert problem solvers are able to recognize problem structure and disregard problem setting, as compared to novice and less successful problem solvers who attend to setting first. There is a paucity of research on young students' categorization of algebraic problems. The reported study promotes a better understanding of 4-6 grade students' perception of problem similarity and gains insight into the students' reasoning processes as they compare algebraic problems with several unknowns by difficulty and by likeness.

To find out whether young students categorize algebraic problems by setting or by structure, 25 students were interviewed prior to any formal instruction in algebra. An interview protocol was designed to provide consistency of the interview format. The interview included four parts. The first part of the interview helped students become comfortable talking aloud and describing their step-by-step procedures. The second part of the interview was designed to have students clarify methods they employed while solving the problems. They were asked to recall the solution methods they used and provide rationales for their solution steps (Dobrynina, 2001). The third part of the interview required students to order problems by difficulty. Students were asked to select the easiest and most difficult problem from among the two-variable problems and then repeat the procedure for the three-variable problems. With every selection, students were prompted to provide a rationale. The fourth part of the interview required students to consider all six problems, group those they thought were most alike, and provide a justification for each grouping. The results of the third and fourth parts of the interview are the focus of this paper.

The study used six problems: three problems in the study contained two variables and three problems contained three variables (unknowns) and relationships among variables were represented as systems of two or three linear equations. Symbolic representations of problem structures are shown below. In the equations,  $x$ ,  $y$ , and  $z$  are unknowns and  $A$ ,  $B$ ,  $C$ ,  $D$ , and  $E$  are natural numbers less than 30.

$$(1) \quad 3x + y = A$$

$$2x + y = B$$

$$x = ? \quad y = ?$$

$$(2) \quad 2x + y + z = C$$

$$x + y + z = D$$

$$2x + y = E$$

$$x = ? \quad y = ? \quad z = ?$$

Each structure was represented in three settings. Three problem settings were used to present the two- and three-variable problems: weight scales, advertisements, and frame equations. Weight scales and advertisements utilized pictorial presentations with information in text. Frame equations, by contrast, employed an abstract presentation with the same text information. Below is an example of two-variable weight scale problem.

What is the weight of each block?

- Same blocks have same weights.
- Different blocks have different weights.

### Results of the Study

Students were asked to compare six problems, group those that are “alike”, present as many problem groupings as they desired, and provide reasons for their groupings. More than 50% of students stated that all six problems were alike because they could be solved by the same algebraic reasoning method, specifically, “You can always find the difference between pictures to find a missing thing (value), and then you can replace this found value in other pictures to figure out the rest of the object(s) (unknowns).”

Fifteen students stated that the six problems could be put into two groups: one group of two-variable problems and one group of three-variable problems. Reasons for this grouping included: "There is one less thing to consider in the first three problems than in the last three"; "There is one more step to take in the last three problems than in the first three"; "The number of pictures to look at is different, and number of things to figure out is different." Since students were asked to present as many groupings as they wanted, eight of the 15 students who put six problems into two groups, also grouped all six problems together. Fourteen students suggested that the six problems could be put into three groups as follows: weight scales, toys and geometric shapes. Reasons for this grouping involved descriptions of the nature of the unknowns as blocks, toys, or shapes. These fourteen students also stated that the six problems could be grouped differently. Thus problem setting grouping was not the only way the students viewed problem likeness. They grouped problems by solution method and by number of variables, as well.

The results of the study revealed that young students could group problems as "alike" based problem structure or nature of solution strategy. Furthermore, they were able to recognize similarities among problems despite differences in settings. This findings are in concurrence with Krutetskii (1976) who found that mathematically talented students of 7 to 10 year old were able to detect problem structure and ignore problem context; abilities that are crucial to obtaining mathematical information and solving problems (Schoenfeld, 1985).

When comparing the problems by difficulty, seven students selected the frame equation as the "easiest" problem, three students selected the weight problem, and one student selected the advertisement problem. When asked to provide rationales for selecting the frame equation as the easiest problem, students gave the following reasons: "I had practice with problems #1 and #2"; "The same strategy (comparison) can be used here as for the first two problems"; and "It is easy to find a difference here." For the "hardest" problem, six students named the weight problem, three students named the advertisement problem, and two students named the frame equation. When asked to provide justifications for their choices of the weight problem as the most difficult, students gave the following reasons: "It was a completely new problem for me"; "I had no clue how to start; and "I did not see a pattern at first."

Fourteen students declared that all two-variable problems were of equal difficulty. When those students were prompted to elaborate on reasons for their decisions, they said: "In all three problems you can compare A and B and find the missing object"; "The problems are set up differently but you can use the same strategy to solve them"; "You can use the same steps to find two things because one picture (A) has three of the same things and one of another, and the second picture (B) has two of the same things and one of another, so B has one less thing than A"; and "All problems have four objects in A and one object is taken away in B." Students' comparisons of three-variable problems and rationales for their ranking revealed similar results.

In summary, it was surprising that more than 50% of 4-6 grade students were not distracted by problem setting when they compared and ranked problems by difficulty and grouped them by likeness. Students recognized problems that had similar mathematical structures. They did not use algebraic terminology such as variable or unknown when they compared problems and provided reasons for their selections. Students did, however, use their own names to refer to unknowns, calling them “things” or “objects.” The study revealed that elementary school students could solve and compare challenging problems with several unknowns without prior instruction. The results implied that algebraic instruction might begin earlier than upper middle grade school. To gain greater insight into this possibility and to determine the level of assistance students need, the “think aloud” algebraic problem solving might be accompanied by prompts, probes or solution hints.

## STUDENTS' CONCEPTUALIZATIONS IN A SETTING THAT INVOLVES COVARIATION BETWEEN FUNCTION AND RATE OF CHANGE

Juan Estrada  
Facultad de Ingeniería  
Universidad Nacional Autónoma de México  
estrada@servidor.unam.mx

This study documents engineering students' conceptualization when they were requested to interpret a graph that represents the filling of a tank with a variable in-flow of water, but at the same time, there is a tap with a constant out-flow (10 liters/second). The only tap that has control is the in-flow of water. The focus of the study was to observe, how the students interpret relevant aspects of the graph, but in terms of the *manipulation* of the tap which controls the in-flow (e.g., What happens with the tap in the maximum, minimum or inflection points? Is it being opened or does it being shut or remain fixed?) That is, we want to see if the students can make any connection between the covariation of volume and the change of in-flow represented by the action of opening or shutting the tap.

### Introduction

To assess student's understanding of calculus concepts, it is important that they are able to make significant connections between the mathematical ideas seen in a course and be able to apply them to interpret and describe e.g., the graph below. Thompson (1994) has pointed out that coordination of images of rate and rate of change are fundamental to reason about accumulation. In the same vein Carlson et al. (2001) states that covariational thinking is basic "in the development of students' understanding of the major conceptual strands of calculus" (p. 145).

### Subjects, Methods and Procedures

The participants were twenty students that had taken a differential calculus course at a public university of Mexico. The graph (volume versus time) used in the study was:

The students were asked to make a description of the graph in terms of the actions of the tap that controls the in-flow of water, e.g., “at what time-intervals is the tap being opened, being shut or does it remain fixed or it is completely shut?”

### Features of the Task

Analyzing what happens with the handling of the tap that controls the in-flow of the water in the tank based on the graph is not an evident issue e.g.. Is it enough (sufficient) to focus on the volume's increase or decrease (represented in the graph) to determine what is occurring to the tap in terms of being opened or shut? Is it necessary to attend simultaneously the fluctuations of *net* consumptions (first derivative = inflow *minus* outflow, with constant out-flow) and associate these ideas with dynamic geometrical view point (enact or imagine the behavior of tangent line over the curve as the time varying in the functions' domain, and therefore observe the changes in the value of the slope) The establishment of these connections are crucial in order to analyze what happens with the handling of the tap, e.g., if the first derivative is positive it means that the in-flow is larger than the out-flow, but this data is not sufficient to know if the tap is being opened or being shut. We need the information of the changes of the *net* consumption. This gives the information about how the curve is bending. Both data allow to determine if the tap is being opened or being shut. In order to, help the students to analyze the situation, the first derivative (a concept) can be *manipulated* through the actions to open or shut the tap. We assume that this tangible support can promote the student's development of connections (rate of change and changing rate of change)

The data was gathered from a questionnaire and an interview. The former contained fifteen questions. The answers were categorized in highlight tendencies. The concepts involved were: increase or decrease function, first derivative, maximum and minimum, change of concavity and inflexion points. As an illustration, some questions of the questionnaire were:

“At what time-intervals does the change of in-flow increase or decrease?”

“At what instant is the in-flow the same as the out-flow?” (maximum and minimum)

“At what instant does the tap which was being shut begin to be opened or vice versa?” (inflexion points)

### Presentation of Results

The most recurrent conceptualization was the students noting the increase or decrease of volume represented in the graph, as the key aspect to determine if the tap which controls the in-flow was being opened or being shut that is if the volume increases or decreases, then the tap is being opened or being shut (“we know when the tap is opened because the graph shows an increase of the volume and being shut

because it shows a decrease of the volume”) Noted that the students left aside or didn’t see the change of net consumption (first derivative) as relevant information for the analysis of what happens with the tap. This misconception leads the students to another misunderstanding about what happens at maximum and minimum points e.g., “the tap is shut in the maximum point and is open in the minimum point”.

Most of the students were not able to link the handling of the tap going from opening to shutting or vice versa with the change of concavity or inflexion points. These actions were associated with what happened at the maximum and minimum points, e.g., “the tap is being shut and being opened in the maximum or minimum”.

### Conclusions

The framework of Carlson, et al. (2001), permits to explain the above misconceptions: the students showed a lack or loose coordination of how the variables are changing with respect to each other [e.g., volume (function) and first derivative (net consumption)]. These findings, in addition to the fact that the students confused the volume with the change of the in-flow, caused an ill interpretation of the graph. In spite of these difficulties, we believe that this type of tasks has potential to assess the mathematical ideas in calculus and promote student to connect ideas, thus to achieve a comprehensive learning.

**UNDERSTANDING STUDENTS' COGNITIVE TENDENCIES  
IN SOLVING ALGEBRAIC PROBLEMS:  
AN EXPLORATORY STUDY**

Fenqjen Luo  
Chung Yu Junior College of Business Administration  
luofj@yahoo.com.tw

The main purpose of this paper is to construct an understanding of low achievement students' cognitive tendencies in solving algebraic problems. In terms of cognitive development, it is an interesting exploratory to go through some processes of algebraic expressions and analyze the abstract levels. The common cognitive tendencies in processing the algebraic expressions between the more concrete and the more abstract were highlighted in this paper. Forty-four students, enrolled in my 1st-year Junior College Mathematics core course, participated in this study during the 2001-2002 school year. It was found that their cognitive tendencies were trapped in a lower and/or more intuitive level of algebraic expressions. This research proposes another picture of students' algebraic thinking. The recognition of students' algebraic thinking may serve as a basis to improve school algebra curriculum and instruction.

The foundation for the research is a proposed theoretical framework that originated from the perspectives of historical development and cognitive development in mathematics. From historical perspectives, the development of algebraic concepts has been classified into two constructs: expression and abstraction (Boyer, 1991). These two constructs serve as a base of cognitive framework for this study. In school mathematics the learner is expected to translate algebraic expressions between the more concrete and the more abstract and vice versa (Fillooy & Sutherland, 1996). Learning to operate fluently in algebraic expressions, to organize them and to represent them in alternative forms is the key ability to find exact solutions for equations. The process of finding solutions for equations has always been conceived essentially as the heart of algebra curriculum. In this study, by observing how these participating students find solutions for equations or/and inequalities, I identified these participating students' cognitive tendencies in dealing with algebraic expressions. On the other hand, the process of abstraction leads to the formation of mathematics structures of higher order and broader generalization (Skemp, 1987). It is interesting to know these students' cognitive tendencies in formatting new algebraic expressions with respect to each abstract order and/or generalization.

As a teacher-researcher, empirical data were collected through my own mathematics classroom in a natural setting. Forty-four students, who were considered to have low achievements in mathematics, participated in this study during the 2001-2002 school year. All participating students were invited to complete two problem-solving tasks. Each problem-solving task consisted of twenty algebraic problems. These algebraic problems were constructed on the basis of junior high school algebra

curriculum. They were carefully designed to reflect these students' cognitive tendencies of algebraic expressions at different levels of abstraction. For example, how these students solved a first-degree equation and a second-degree equation respectively was assumed to show their tendencies of algebraic expressions at successive abstraction. The writing samples of two problem-solving tasks from these students were mainly used to interpret these students' cognitive tendencies in algebra. Semi-structured interviews, which conducted to these participants, were utilized to support the interpretations of their writing samples. The predetermined theoretical framework was applied to explain the collected data. It was found that the cognitive processes of these students were trapped in a lower and/or more intuitive level of algebraic expressions. These students tended to (a) recognize a given structure of algebraic expressions to an elementary one, (b) avoid the manipulation of algebraic symbols in expressions, (c) decompose all the quantities, (d) prefer more intuitive and natural numbers as answers, or/and (e) represent a quadratic function as a linear graph. This study shows that students with low achievement in mathematics tend to over simplify the algebraic expressions and abstraction because they have difficulties with higher order structures and formalism.

## USES OF CURRICULUM MATERIALS IN HIGH-SCHOOL ALGEBRA: THE CASE OF AN "OLD-FASHIONED" TEACHER

Vilma Mesa  
University of Michigan  
vmesa@umich.edu

This paper reports preliminary results of a larger study conducted to explore the nature of algebra teachers' pedagogical content knowledge, by looking at how teachers use curriculum materials in high-school algebra courses. Research in the learning of school algebra has shown that students apply the rules of symbolic manipulation without understanding the reasons behind them and that many of the recurrent mistakes are a consequence of such lack of understanding (Bednarz, Kieran, & Lee, 1996). The quality of teaching, more than curriculum (e.g., textbooks) has been signaled as a source for such outcomes, but so far little has been done to understand the relationship between teachers and textbooks, and in general, to understand the nature of the knowledge that is needed to teach algebra. I am interested in learning how and why high-school teachers select, modify, and use textbook content in teaching algebra and in using this knowledge to understand the impact of reform in the teaching algebra.

### Theoretical Perspectives

I used Artigue's and colleagues' framework (Artigue, Assude, Grugeon, & Lenfant, 2001) which describes three interrelated dimensions of knowledge: Epistemological (ED), Cognitive (CD), and Didactical (DD) that influence different "professional gestures" and the competencies that teachers exhibit in their teaching of algebra. The framework is compatible with and complementary to Shulman's (1986) categorization of knowledge and it is useful because it articulates characteristics of teachers' knowledge particular to algebra. The ED encompasses notions about the historical development of algebra, the distinction between object and tool (Douady, 1984), and notions about the mathematical structure of algebra. The CD includes knowledge about general learning theories, difficulties and misunderstandings with algebra, problems of the relation between algebra and arithmetic, and knowledge of meaning of different semiotic representations (graphs, symbols). The DD includes knowledge of the curriculum organization (e.g., goals of algebraic teaching by grade or progression of tasks), textbooks, reform materials, tests, motivation, and so forth (Artigue et al., pp. 26-27). In this study, the emphasis is on teachers' curricular knowledge within the didactical dimension. In particular I posed the following question: how do teachers use textbooks and other materials to define an algebra curriculum? I report here results of a pilot case study that explored this question.

### Methods and Data Sources

I conducted a case study (Stake, 1995) of an algebra teacher who teaches algebra 1 in a small (450 students) magnet high school in the Midwest. The teacher had

the freedom to select the textbooks for his classes. After working with an integrated curriculum for a year, he chose an “old-fashioned” algebra textbook (Dressler, 2000) which offers a sharp contrast with the standards-based curricula students have encountered in all their previous schooling. With this case study I wanted to single out issues that would be pursued as hypothesis in future studies about the nature of knowledge needed for teaching algebra. Data came from weekly class observations, notes, and debriefing; videotapes of selected classes; collection of textbook materials, worksheets, tests, and other written activities developed by the teacher; and three types of teacher interviews: linked to particular lessons, general interviews in which particular problems and questions were posed, and video-tape interviews, in which the teacher and the researcher observed segments of his teaching and discussed its potential for creating discussions for future secondary teachers. Data were collected in the academic year 2001-2002 and were codified into broad categories according to the three dimensions of knowledge with further data collection used to refine and provide descriptions for sub-themes, a method consistent with the constant comparative analysis (Corbin & Strauss, 1990). The teacher read documents produced by the researcher to test for validity of the assertions.

### Results

Derek is an engineer by training and became a teacher after 5+ years in business for personal reasons; he holds a master’s in mathematics and has been teaching in this high school for 9 years “just when the [NCTM] Standards were published.” He selected the textbook (Dressler, 2000) over other “integrated” because he feels “very comfortable with everything [it is] doing” he thinks the material is learnable and consistent whereas the other [integrated] books “I needed to jump around, I either liked the material or the problems and I felt that there was always something new and no continuity.” He sensed a lack of focus and was unable to “cover all the material; I felt that it was difficult to develop the ideas... This book is simple, clear for teaching and learning; and has plenty of examples and problems.” He follows the textbook, uses most of the examples in instruction, and assigns almost all (either the even or the odd) problems in each section, occasionally skipping some lessons (about 4 in all). He supplements with two types of worksheets, puzzle-type (Marcy, 1983), because with these “students can check by themselves whether their work is correct” and teacher-created type, which usually contain problems taken from examples drawn from Dressler (2000) or from other textbooks. Derek describes this class as a “normal group of kids” and frequently highlights that one of his goals is for students to be autonomous in their learning. One of the manifestations of this goal is his decision of not using class-time for checking homework—which consists of about 15 problems taken from the book, assigned weekly—because “some kids do learn without doing every [assigned] problem” and because “they are old enough” to be responsible for their own learning and assume the consequences of not practicing. Students receive extra points in tests when

they do their homework. On rare occasions Derek has brought ideas not present in the textbook (e.g., big Xs to find two integers that added or multiplied give two given numbers) but had not attempted to link them to the content studied. The class has a relaxed atmosphere, with students freely raising questions and volunteering answers, and a special sense of togetherness. Most of the time students work individually but in groups helping each other and much of their talk is about personal issues. Students have acknowledged publicly their appreciation for the class and their sense that they are learning a “lot of stuff” and that they feel “very capable of doing mathematics, more than anytime before” some for the first time. During class Derek frequently remarks the importance of working hard and learning the materials and in all the interviews, he has talked about how the reform has fallen short in providing answers to pressing questions of teaching and learning. I have observed a continuous and uniform progress in students’ ability in solving the problems posed in the textbook.

### Discussion

The question that I sought to answer—how a teacher’s use of curriculum materials defines an Algebra 1 curriculum—falls within the realm of the DD of the framework but the other dimensions (ED, CD) were present and relevant for the analysis. Two themes helped in explaining this teacher’s professional gestures with respect to his selection, use, and modification of curriculum materials in algebra: “Algebra is a tool for future work” (ED, DD) and “Ambivalence about reform” (DD, CD). Derek’s view of algebra as a tool is pervasive in his talk and work. Epistemologically algebra consists of “algebraic manipulations, modeling world problems using variables and solving equations” a knowledge that makes a “well rounded person” and enables one to “pursue any career.” Didactically this view of algebra justifies his selection of textbook and other materials because that is knowledge “you can put your hands on,” meaning you know when it is new and when it is not. Derek’s ambivalence about the reform is also present in his talk and work. His view of the reform curricula as treating too many topics which do not do justice to any of them has implications in his didactical choice of the textbook; a choice that is also supported by his cognitive knowledge: the reform curricula do not take advantage of students’ capabilities of making abstractions because there is “so much emphasis in concrete work, with problems that are not real for the students” and so little room for abstraction that it makes the “students think that they are just doing the same thing over and over again.”

Derek has a reasonable mathematical preparation and experience and has welcomed the reform; but he has used reform textbooks that have done a poor job in maintaining the purpose and abstract complexity of algebra. As a person with autonomy to make a choice, he consciously rejects alternatives that researchers see as fostering a greater and deeper engagement with the subject because from *his* point of view, students’ engagement comes from having a sense of control of what they are learning. A critical textbook analysis of reformed curricula could illuminate whether indeed stu-

dents can not experience such sense of control and a study on how teachers cope with engagement with the subject matter given in the curriculum is then urgently needed.

## **THE EFFECT OF A MULTIPLE REPRESENTATION-BASED ALGEBRA CURRICULUM ON A STUDENTS CONCEPTUAL UNDERSTANDING OF FUNCTIONS**

Karen S. Norwood  
North Carolina State University  
karen\_norwood@ncsu.edu

This study focused on examining the students' ability to make connections between the different representations and the students' ability to use the various forms to solve quadratic equations. The students showed a significant increase in their level of understanding through the use of a multiple representation-based curriculum.

There is an agreement among mathematics educators about the importance of the function concept in high school mathematics (NCTM, 2000). Lloyd and Wilson (1998) state that it is important to remember that one representation of a function may have "varying limitations or strengths in different contexts" (p. 253); therefore the ability to move among the representations is necessary to be able to interpret various problem situations.

### **Theoretical Framework**

For the purposes of this paper, multiple representations refers to the presentation of a concept or process using numerical, graphical, and symbolic viewpoints (Noble, Nemirovsky, Wright, & Tierney, 2001; Porzio 1999). Skemp (1979) described conceptual representations as schemas or structures that are constructed by relating other concepts or objects to one another.

### **Objectives**

This study was focused on examining the students' ability to make connections between the different representations and the students' ability to use this knowledge to categorize the cards into groups that represent the same functions using different representations. The purpose of the research is: 1) to determine whether students are able to make the connections among the various representations of functions, and 2) to determine whether students' ability to make the connections among the representations can be influenced by teaching that stresses connections between representations.

### **Methods Of Inquiry And Data Sources**

The setting for the study was a large southeastern university. The students were enrolled in two different sections of an intermediate algebra course. The students in the classes participated in lectures, used graphing calculators for class work, homework, quizzes, and tests, classroom discussions, group activities, and submitted their homework online. The study was conducted during a 15-week constructivist teaching experiment, including pre and post task-based interviews. The subjects were taught in

a class that emphasized and encouraged the use of multiple representations. Pre and post function sorts were conducted with individual students. These function sorts were videotaped and questioning was employed to determine student reasoning behind a particular sort. The teacher-researcher and a non-participant observer analyzed these videotapes. The type of sort they perform will be analyzed by the teacher-researcher and an observer to determine the level of thinking behind the sort. The levels of thinking will be classified according to the following table:

| Level of Sort | Type of sort                                     | Example   | Level of Mathematical Connections  |
|---------------|--|---|--|
| 1             | Surface sort                                     | Student sorts graphs in one pile, tables in one pile and algebraic representations in a pile  | No connections between representations   |
| 2             | Surface sort with some additional sorting factor | Student puts the graphs together, tables together and algebraic representations together; use some mathematical scheme to separate further, e.g. put all quadratic graphs together, all linear graphs together, all linear equations together, etc. | No connections between representations, but some mathematical understanding about the type of representation |
| 3             | Partial Connection Sort                          | Student puts the graph of one type of function with either the equations or table of values of the same type of function; the graphs of linear functions together with one of the other types of the same function                                  | Connections between representations are being made, though not between all three representations             |
| 4             | Full Connection Sort                             | Student places the tables, graphs and algebraic representations of the same function together   | Connections are being made between all three representations.  |

Figure 1. Sample of 3 types of cards used in card sort.

The number of students moving from a level with no connections to a level in which connections were made and analyzed using a distribution-free signed rank test (Wilcoxon) to determine if the number students making connections between the representations has increased.

### Results

The a Wilcoxon Signed Rank Test indicated that there was enough evidence to state that there was a difference in conceptual levels of students between the pre and post-card sort when teaching using a multiple representation-based curriculum. The sort level of the students' increased 1-2 levels after they had been taught function concepts using a multiple representation-based curriculum.

| Subject | Pre-Sort | Post-Sort | Difference |
|---------|----------|-----------|------------|
| 1       | 2        | 4         | 2          |
| 2       | 1        | 2         | 1          |
| 3       | 1        | 2         | 1          |
| 4       | 1        | 3         | 2          |
| 5       | 1        | 3         | 2          |

$$n = 15$$

$$\text{Wilcoxon Statistic} = 15$$

$$p = .03 \text{ (significant)}$$

$$\text{Achieved Confidence} = 96\%$$

$$\text{Confidence Interval is } (1.00, 2.00)$$

### Conclusions

The a Wilcoxon Signed Rank Test indicated a significant strengthening in students connections between representations which would allow students to be more flexible with the representation they use to solve a problem and to move more freely between the representations. Therefore, multiple representation-based curriculum should be used in the teaching of function concepts. As educators, we need to help students make the connections between the various representations.

## SYSTEM OF EQUATIONS AND ALGEBRAIC SUBSTITUTION: SYNTAX AND SIGNIFICANCE EXTENSION

Armando Solares  
CINVESTAV, México  
asolares@mail.cinvestav.mx

It is of interest to describe both the way in which children apply a learned syntax in order to solve linear equations with an unknown (using a geometric model) to a *system of linear equations with two unknowns*, as well as the new significances obtained through this extension process. In this presentation we analyze the way in which 12 to 13 years old children begin to solve a system of linear equations both within the context of word problems solution and that of pure syntactic solution.

### Background

Following the research program proposed by Filloy, Puig and Rojano (Rojano, 1994), which aims to clarify the details of algebraic language acquisition, we accept the *Local theoretical models* (Filloy, 1990) as our theoretical framework. From this perspective, the use of *algebraic substitution* implies an abstraction level --both in the interpretation and in the use of algebraic symbols-- higher than that needed to operate with a single unknown in the solution of one linear equation. Specially regarding the solution of certain system of equations such as (S):

$$4x - 3 = y$$

$$6x = y - 7$$

The *algebraic substitution* entails putting into practice the idea that *an unknown* which represents an unknown quantity *can be expressed in terms of another unknown*. So, a problem with two unknowns can be reduced to a problem with just one unknown quantity and then it is possible to apply the syntactic skills previously learned so as to solve linear equations involving one unknown.

When dealing with algebraic substitution the idea of the unknown becomes more complex, since algebraic expressions are used to represent unknowns. Moreover, algebraic relation and algebraic transformation do change. For example, the idea of equivalent equations and transformations that can be applied to obtain equivalent equations is extended (e.g., see Freudenthal, 1983; Kieran, 1998; Matz, 1980).

The theoretical framework of *Local theoretical models* provides the semiotic tools to analyze these different levels of complexity, permitting both the study of the mathematical formal meaning of these concepts and of the meaning assigned by their use for solving problems: their *pragmatic meaning* (Filloy & Kieran, 1989). This theoretical framework allows, then, the study of strategies and *intermediate codes* produced by the learner as he or she becomes more competent in the use of mathematical knowledge.

### Analysis Results

In this presentation, Manuel and Mariana's cases are analyzed (P and Mr, respectively). These cases belong to the study *La adquisición del lenguaje algebraico: la operación de la incógnita* developed by E. Filloy and T. Rojano (Rojano, 1984; Filloy & Rojano, 1989, 2001). Here the analysis is carried out coming from the view of the research project *School algebra as a language: the first algebraic syntax and semantics elements* (Solares, 2001). Within our project a clinical study with children from 12 to 14 years old is being carried out at a school center in Mexico, and the results and questions that arose from the afore mentioned previous project are being reformulated:

What are the difficulties derived by the learning of *algebraic substitution* when solving verbal and syntax problems with two unknowns? How do learners extend their already learned syntax in order to solve equations with just one unknown?

The analysis of the interviews with P and Mr offer evidence that allow us to say that *algebraic substitution* is essential for manipulating the unknown.

When a competent subject makes the *algebraic substitution* he or she uses the equivalence of two algebraic expressions. For example, in the system (S) a competent user considers as equivalent the expressions " $4x - 3$ " and " $y$ ", for him or her these are names of the same object: the corresponding algebraic function. In contrast with this, we have that spontaneous reading by children can be centered upon the operations necessary to calculate the value of " $y$ ". This difference on meanings attributed to the algebraic expressions is recurrent in algebra teaching, in which case the teacher is a competent user and the pupils are learners, generating thus difficulties not clarified yet by research.

Also, the analysis of these interviews shows that those children that have become competent users in the *manipulation of the unknown* (Filloy & Rojano, 1989) generate solution-strategies for verbal and syntactic problems with two unknowns. These strategies can either become obstacles for the learning of equation systems, or general methods for their resolution –thus the necessity for their study.

For example, when solving problems, children can express an unknown in terms of the other by using the context. And when solving equation systems they can develop strategies based upon the extension of the arithmetical use of the sign 'equal', as P did. He constructs the transformation consisting in the addition of a same amount to both members of an equation. This transformation maintains both the equivalence of members and the value of the operated unknowns. Thus, besides numbers or identical expressions, P is able to add complete algebraic expressions as long as they are equivalent (in order to solve systems like (S)):

P. "...now I will combine these two (both equations), I have " $10x - 3 = 2x - 7$ " (he added both equations), and I have to eliminate this "-3" here and as a result I have " $10x = 2y - 4$ "; now I will use the *criss-cross method* which gives me as a result..." $4x + y - 10 = 6x + y$ ", (he adds the left member of one of the equations to the right one of the other), now I will simplify as much as possible, I eliminate " $4x$ ", the result is " $2x$ " here I eliminate the " $y$ 's" and the result is " $2x = -10$ " from which I may deduce that " $x = -5$ ", then ..."

Lastly, this analysis suggests the existence of the risk of generating syntactical errors during the extension process of the notion of the unknown and its syntactical manipulation, providing a perspective for the analysis of certain algebra syntax errors different from those presented by Matz (1980) and Booth (1984) (refer to Filloy, Rojano, & Solares, 2002).

## COGNITIVE TENDENCIES IN THE SOLVING WORD ALGEBRAIC PROBLEMS USING SYMBOLIC MANIPULATORS: CLINICAL STUDY ON THE ALGEBRAIC SYNTAX-SEMANTICS RELATIONSHIP

Miguel Benito Huesca Esparza  
CINVESTAV- México  
mariacallas@tutopia.com

The objective of this investigation is:

1. To carry out lessons in the symbolic manipulator's screen, making the student to meditate on what has and what brings in her again (formulas, algorithms, etc.) so that he generates and use algebraic expressions with the purpose of exploring, to discover and to manipulate things that he ignored. Beginning this way the observation stage.
2. To investigate the way as the symbolic manipulators using for represent and solve word algebraic problems by students, relating them with their previously arithmetic experiences and the progressive use of the Mathematical System of Signs algebraic.
3. To characterize cognitive tendencies, product of solving word algebraic problems to take the part to the students, using the symbolic manipulators.

The fellows that begin in the learning of the school algebra face the necessity of developing an operability it has more than about symbols that not very before corresponded to relating and meaning sources characteristic of the Arithmetic, but that now they have, completely different senses. These phenomena can be studied from a point of view that considers to this school content as a Mathematical System of Signs in use. With foundation in the above mentioned and with the use of symbolic manipulators, as a programmable calculators, it is sought to create an atmosphere for modeling and solving word algebraic problems, in which think about interesting queries in the algebraic syntax-semantics relationship. Interesting results in the solving arithmetic-algebraic problems, were given with didactic models that put emphasis in the necessity of being competent in more and more abstract and general uses of the logical-mental representations that are required to par excellence reach a full competition in the algebraic method, the Cartesian method (MC), this necessity, is the one that contrasts this method with the competitions that required other two: the method of successive analytic inferences (MIAS) and the analytic method of successive explorations (MAES). The analysis of these models guides and they tune the formulation of verbal algebraic problems that they generate and propitiate the use of algebraic expressions, with the purpose that the students explore, discover, meditate, manipulate, check, operate and validate the things that they ignore and this appear in the symbolic manipulator (formulas, algorithms, etc.) and that they can move, to cut, to erase, and to invoke when it is wanted.

In the investigation utilizing the theoretical and methodological proposal of the Theoretical Models Local, and the notion of Mathematical System of Signs. The Theoretical Models Local doesn't privilege some component grammar, logic, mathematics, cognitive, pragmatic, of teaching or of communication, rather it builds Models Theoretical Local only adapted for specific phenomena but able of taking into account their four components; Teaching models, models of Processes Cognitive, models of Formal Competition and Communication models.

It is necessary also to use a notion of sufficiently wide of Mathematical System of Signs, so that it serves as tool of analysis of the texts that the students take place –these texts are conceived as the result of processes of sense production- since the Mathematical System of Signs is the product of a process of progressive abstraction, either in the History of the Mathematics or in the personal history of the student. The stratification of the Mathematical System of Signs is a result of this process. They are studied then, Mathematical System of Signs intermissions, together with their corresponding personal codes –that the students invents- to discover the obstructions that take place to try with different available Mathematical System of Signs, while he is trying to be competent in the use of a new Mathematical System of Signs and of having a good performance in terms of the pragmatic meaning certain socially.

## **CAN STUDENTS' USE OF REPRESENTATIONS BE INFLUENCED BY TEACHING?**

Robin L. Rider  
North Carolina State University  
rlrider@unity.ncsu.edu

It is the purpose of this research to determine if teaching with multiple representations will enable the college level remedial math student to broaden their network of mathematical knowledge and allow them to see familiar concepts in a new light so that they can construct meaning for the concepts and claim ownership of them. The hypothesis is that this expanded network of related concepts will allow them to choose to a representation other than symbolic manipulation to solve a problem when convenient and applicable.

Studying the effect of teaching on student use of different representations to solve problems will promote deeper and better understanding of the psychological aspects of learning mathematics. If a link is established between a method of teaching encouraging the use of multiple representations and a students' willingness to change from traditional algebraic manipulations to using an alternate representation to solve problems, classroom teaching can be modified to help students move freely between representations. This will enhance their mathematical understanding and increasing the structure and hierarchies of their networks of mathematical knowledge.

Experience strongly influences what representation a student will choose to use to solve a problem (Keller & Hirsch, 1998). "Because each representational format has varying limitations or strengths in different contexts, it is beneficial to have the choice of which representations to employ and the knowledge needed to make such a choice" (Lloyd & Wilson, 1998, p. 253). For students to have this choice and this knowledge, they must have experience with each different type of representation. "Mathematics teachers' help students learn to use representations flexibly and appropriately by encouraging them as they create and use representations to support their thinking and communication" (National Council of Teachers of Mathematics, 2000, p. 284).

This study examined students' choice of representation (algebraic, graphical or tabular supplied on the testing instrument) to solve five basic algebra problems. The 13 students who participated in the study took a pretest and a posttest and the type of representation they used to solve the problem was recorded. On the pretest if the student did not know how to solve the problem, he or she was asked to select the representation that was most familiar or with which they were most likely to use to solve the problem. Because of the small sample size and unknown distribution of the data, a nonparametric Wilcoxon Signed Rank Test was used to evaluate the significance of the differences between the number of problems the students solved algebraically and the number of problems the students solved either graphically or with a table on the pre-

test. The same was done on the posttest. The pretest showed no significant difference between using algebraic and using a graph or a table (testing a two-sided alternative for a difference obtained a p-value of .485). The posttest showed a significant change in method of solving the problem. The difference between the number of times a student chose to solve a problem algebraically was significantly less than alternative methods (testing a one-sided alternative for a difference between number of times a student used algebraic methods vs. the number of times a student used an alternative method was less than 0 obtained a p-value of .002).

This study is a preliminary study examining the effects of teaching with multiple representations on student choices in how to solve a basic algebra problem. The study found that students can be influenced to choose an alternative way to solve a problem when taught several different ways to interpret a problem. There was no indication in the study that students abandoned symbolic manipulation altogether, rather the evidence seems to suggest that students incorporate other methods of solving problems in their network of knowledge of algebra, and move from one representation to another with equal consistency.

## **History and Aims of the PME Group**

PME came into existence at the Third International Congress on Mathematical Education (ICME 3) held in Karlsruhe, Germany in 1976. It is affiliated with the International Commission for Mathematical Instruction.

The major goals of the International Group and the North American Chapter are:

1. To promote international contacts and the exchange of scientific information in the psychology of mathematics education.
2. To promote and stimulate interdisciplinary research in the aforesaid area with the cooperation of psychologists, mathematicians and mathematics educators.
3. To further a deeper and better understanding of the psychological aspects of teaching and learning mathematics and the implementation thereof.

## Preface

It is with great pleasure that we at the University of Georgia host the 24<sup>th</sup> annual meeting of PME-NA as we also hosted the 4<sup>th</sup> annual PME-NA meeting exactly 20 years ago in 1982. A quick glance at the differences between then and now shows how the field has grown and changed: The proceedings that year were about 250 pages long, and there were 34 papers presented in 7 topic areas. This year the proceedings will be nearly 2000 pages long with over 200 presentations in 15 topic areas. Despite the growth of the field and the organization, the hallmarks of collegiality and open intellectual exchange remain.

The theme of this year's conference is *Linking Research and Practice*. The theme is intended to highlight the interplay between the ways that research is used in practice and the ways that research grows out of practice. The invited plenary speakers were asked to address the theme in their areas of expertise by challenging the audience to think critically about the research we do—the questions we ask, the methods we use, the contexts in which we do research, the people with whom we do research, how we communicate the results of our research, etc. We hope that those in attendance as well as those who will read these papers in years to come will be stimulated to think deeply about our roles as researchers and consumers of research.

We received over 250 proposals for sessions at PME-NA and are grateful for the work of the many reviewers who helped shape the program. We undertook only structural editing (format and references) on the final papers so as to leave intact the integrity of the authors' work.

We wish to express our appreciation to the many people at the University of Georgia who have made these volumes and this conference a possibility, including, but not limited to, Patricia S. Wilson, Margaret Caufield, Elizabeth Platt, Salli Park, Bernice Peters, Teresa Banker, Nancy Williams, Joseph Allen, Brian Wynne, and all of the faculty and graduate students in the Department of Mathematics Education.

*The Editors*

# Assessment

**A CONTENT ANALYSIS OF EXIT LEVEL MATHEMATICS  
ON THE TEXAS ASSESSMENT OF ACADEMIC SKILLS:  
ADDRESSING THE ISSUE OF INSTRUCTIONAL  
DECISION-MAKING IN TEXAS**

Jere Confrey  
University of Texas at Austin  
jere@mail.utexas.edu

David Carrejo  
University of Texas at Austin  
carrejo@mail.utexas.edu

High stakes tests are increasingly used to monitor systemic improvements in mathematics and teachers are expected to rely on the results of such tests to adapt their instructional practices. We examine the Texas Assessment of Academic Skills (TAAS) over a period of three years to examine to what extent its results can be used to guide instructional decision-making. We present the results of an expert content analysis of the 10<sup>th</sup> grade TAAS mathematics test for 1999, 2000, and 2001 which reveal that problem solving objectives mask significant content emphases. We further examine the variation in raw scores by objective across grades and years to show this information is not reliable enough to guide changes in instruction. We examine the sampling of topics within objective to gauge the distribution across topics. Finally, we attempt unsuccessfully to account for changes in difficulty using a combination of changes in sampling, item characteristics and composition of distractors. This leads us to question the utility of providing teachers raw data by objective and points to the urgency of developing better methods to link content analyses and psychometric methods of scoring.

Since 1995, the state of Texas relied on the Texas Assessment of Academic Skills (TAAS) to drive the current accountability system for Texas schools. Along with attendance and course credits, passage of the TAAS was required for a student to graduate. A new assessment, the Texas Assessment of Knowledge and Skills (TAKS) will be implemented in 2003, and although better aligned with secondary topics, it will produce similar data artifacts for teacher use. TAAS results, in the form of raw scores by test objective, scaled scores known as Texas Learning Index (TLI) scores, and item analysis percentages have been provided to teachers and administrators to guide them in improving school performance and providing quality instruction in mathematics. Our interest was in examining these data to determine if they could validly be used for these purposes. Our interest in the question was piqued by data showing discrepant results as student scores on TLI increased while raw scores have declined, typically explained by the state as differences in test difficulty (Confrey & Carrejo, 2002). We sought to understand at the level of classroom practice, if the data provided by raw score for each of thirteen objectives could be used to make instructional changes, as it is widely believed.

In the case of the TAAS test, we propose that even within a single test and its analyses, drawing data-driven conclusions reveals how psychometric traditions for

creating scaled scores and equated tests seem to produce contrasting results from content analyses. The key issue of content validity (Heubert & Hauser, 1999) “whether a test measures what it purports to measure and what conclusions can be drawn from the results – and whether the conclusions or inferences drawn from the test results are appropriate” (p. 71), requires one to link these two arenas. Thus our goal is to link psychometric and content analytical traditions by building protocols to help teachers refine their analysis and increase their statistical capacity to interpret and critique data and create plans of action (Confrey and Makar, 2002). In addition, we wish to argue for the role of outside content experts when conducting analyses of the TAAS. We argue for more discipline-based protocols for conducting and interpreting item analyses, and point out that these analyses are likely to be neglected or unpublished under the current accountability system.

In this paper, we provide an account of our content analysis of the mathematics portion of the TAAS test for the 10<sup>th</sup> grade level over a period of three years (1999, 2000, and 2001). We address, based on available information, the question, “Can data provided to teachers in the form of raw scores by objective provide an accurate description of student performance and support instructional decision making?” In addressing this question, we relied on answers to three sub-questions:

1. Using an independent content protocol, do the constructed TAAS objectives provide an adequate description of the content tested?
2. How much variation is there in students’ mean performance by these objectives across the grades over time?
3. Can we identify the possible factors that result in changes in performance by objective through a content sampling and item analysis?

As development of the new assessment, TAKS, is underway, examination of the TAAS, its construction, format, and content, provides important experimental groundwork for future analysis of the new test, designed to be closely aligned with TAAS.

### **TAAS Construction and Format**

According to the test makers, the Texas Education Agency (TEA, 2001), construction of the TAAS first involves a review of state standards for mathematics, the Texas Essential Knowledge and Skills (TEKS), to determine appropriate learning objectives by grade level. Following this review, educator committees develop drafts of test objectives, linked to the TEKS, to be reviewed by teachers and other specialists. The objectives are then refined based on feedback, and sample test items are written. Educator committees develop guidelines for assessing each objective which include eligible test content, test item formats, and sample items. A test blueprint is then developed by item writers, some of whom are identified as former teachers. TEA curriculum specialists then review the items. During this process, item review commit-

tees judge the content, difficulty, and bias of each item. Further item revision occurs and then they are field tested. Field-test data is analyzed for reliability, validity, and possible bias. Data review committees then use statistical analyses to determine if items are worthy of being used. The final blueprint is then developed. Field-test items are placed in an item bank and the final tests are built from the bank and are designed to be equivalent in difficulty from one administration to the next.

TEA outlines thirteen objectives grouped in three categories: concepts, operations, and problem solving. Within concepts there are five objectives: (1) Number Concepts, (2) Relations and Functions, (3) Geometric Properties, (4) Measurement, and (5) Probability and Statistics. Within operations are (6) Addition, (7) Subtraction, (8) Multiplication, and (9) Division. Within problem solving are the four remaining objectives: (10) Estimation, (11) Solution Strategies, (12) Representation, and (13) Reasonableness. TAAS questions are clustered in groups of four under each objective with the exception of Solution Strategies and Representations which have eight items each at the exit level. Therefore, sixty questions comprise the final multiple choice exit test with each question having a possible 4-5 answers. Furthermore, TEA outlines which state mathematics standard(s), i.e. TEKS standard(s), is tested by each aforementioned TAAS objective.

### **Examining TAAS Content with an Expert Protocol**

Our approach to the analysis began by:

1. Creating a protocol based on our selection of topics relevant to K-12 mathematics education. The topics comprising the protocol are indicative of the breadth of subject matter teachers and researchers find most relevant to many, if not most, implemented curricula. Topics were also chosen based on current research in mathematics education.
2. Obtaining copies of the tests (available from the TEA website) and categorizing each item according to the constructed protocol without referring to their respective TAAS designation. If a general topic was missing for an item, it was identified and the categories were adapted until we could account for all items on the test.
3. Comparing our categorization with that of TEA's for all three years.

Our protocol includes the following topics (followed by subtopics): a) numeration (scientific notation, sequences), b) geometry (angle, congruency, coordinate plots, formula, spatial reasoning, similarity, symmetry, and vertices, edges, and faces), c) measurement (linear/perimeter, area, volume, weight, and the Pythagorean Theorem), d) operations (addition, subtraction, multiplication, division), e) rate (ratio and proportion), f) probability (combination, experiment outcomes, and mean, median, mode), g) data and statistics, and h) equations (literal, equation with variable, inequality). For d)

operations, we constructed the following table to indicate specific number types used in the items we placed under this topic (see Figure 1).

Likewise for g) data & statistics, we constructed the following table to indicate the representation format involved in the question and the representation involved in the answer choice (see Figure 2).

Our categorization separated the topics of ratio and data analysis as separate categories (see Figure 3).

Our categorization separated the topics of ratio and data analysis as separate categories (see Figure 3). We used it to examine and display content distribution on the test over the three years. The following chart shows the number of items per topic. It is in marked contrast with the test specifications which specify four items per objective for most objectives and eight for solution strategies and representation.

One can see the emphasis on certain topics such as addition and subtraction remain relatively unchanged from year to year. However, other topics such as mul-

|                   | Whole | Integers | Fractions | Decimal | Percent | Exponents |

|               | Circle |             |       |      |     |        |        |

Figure 2.

Figure 3. Distribution of items by topic, 1999, 2000, 2001

tiplication, division, ratio, equations, and data receive different emphasis from year to year. (Notably, measurement received a heavier emphasis in 2001 compared to the previous two years.) The major difference lies in our elimination of the Problem Solving objectives (Estimation, Solution Strategies, Representations, and Reasonableness) and categorization of their items into content categories. The following table lists the item numbers in each of these Objectives and the heading under which we placed them on our protocol (see Figure 4). Also note the variation in topics year to year.

The total number of items in the 1999 test related to multiplicative structures (multiplication, division, ratio, rate) is eighteen out of the sixty items. The total number of items in 2000 is eleven out of the sixty and the total number for 2001 is fifteen out of sixty. We found multiplicative structures far more heavily represented than teachers recognized, and hence its importance in passing TAAS could have been easily neglected. Furthermore, TAAS Objective 5, Probability and Statistics, contains four items, yet on the overall tests, the total number of items related to data, statistics, and probability under our protocol is six out of sixty for 1999, nine out of sixty for 2000, and eight out of sixty for 2001. This area is also underrepresented in the test specifications relative to the actual test. We conclude that constructs in multiplicative structures and data and statistics (including probability) comprise 24 out of 60 or 40% of the items for 1999, 20 out of 60 or 33% of the items for 2000, and 23 out of 60 or 38% of the items for 2001. This analysis indicates how the Problem Solving category with its four Objectives mask content that teachers should emphasize in their instruction. We understand why the Problem Solving objectives were included but point out that they

should be crossed dimensionally with the Content objectives rather than designed as their own categories.

### Variation in Students' Mean Performance by Objective

Our second investigation concerned the variation in student performance for each objective. Teachers were using declines or gains in performance by objective as evidence of instructional need or success. We decided to examine the variation in students' mean scores in two ways. First, we examined student performance for TAAS assessments 1999, 2000, and 2001 disaggregated by objective. Then we examined performance over three years by grade level to see if any trend lines suggested patterns of improvement or decline (see Figure 5).

Figure 5. Variation in mean scores for all grades.

Note that two of the four Objectives related to operations; namely, Objectives 6 & 7 show little variation for all grades. However, Objectives, 4, 5, and 11, Measurement, Probability & Statistics, and Solution Strategies respectively, show considerably more variation. These data raise questions whether raw scores reported by objective are relatively stable enough over time to guide instructional decisions.

One possible explanation for the variation is that students are consistently gaining ground on particular objectives as teachers implement revised strategies for instruction. To examine this question, we examined student performance on the objectives individually by grade over three years. Our analyses revealed little consistency in

results. From 1999-2000, over student performance measures on six Objectives increased, while performance decreased on the remaining seven Objectives. From 2000-2001, student performance increased on two Objectives and decreased on the remaining eleven. These data suggest that variation in student performance by Objective was due to improvements over time. Below, we provide the trend charts for Objectives 4, 5, and 11 for all grades as illustrative of the variation found.

Figure 6. Objective 4 trends for all grades.

Figure 7. Objective 5 trends for all grades.

Figure 8. Objective 7 trends for all grades.

This analysis demonstrates that teachers cannot simply use changes in their mean student performance by objective to guide their planning. This seems obvious as one recognizes that the raw scores by objective are the product of not only the content of the objective but also the sampling of topics and the difficulty of the items and distractors. This led us to our next protocol for analysis.

#### Possible Content Factors Affecting Student Performance by Sampling and Difficulty

Returning to content analytical methods, we tapped into another possible source of information for teachers that could be useful in examining the variation in sampling of subtopics in each objective. TEA outlines which TEKS standards are being aligned with each TAAS objective. We created a table outlining the items clustered under each TAAS Objective. Within each TAAS objective, we identified which associated TEKS standard(s) each Objective tested (TEA, 2000). Each clustered item within a TAAS Objective was aligned with an associated TEKS standard (for example, see Figure 9). Our conjecture was that too little variability would permit the test to lose validity as teachers could virtually drill students on likely topics for inclusion. We expected that a valid test over time would sample proportionately across subtopics. We also expected that if teachers were assuming consistency in certain items, changes in the sampling of those objectives would lead to drops in performance.

Continuing this process for all the TAAS Objectives, we quantified the amount of variability in item sampling between 1999, 2000 and 2001. For example, since two items in 2000 are sampled from a new topic while two items remained from the old topic, we coded this as a 50% change. Eight item objectives can produce changes such

| TEKS standards aligned with TAAS Objective 1:<br>Number Concepts            | 1999  | 2000   | 2001  |
|---|-------|--------|-------|
| (1)(A) compare and order rational numbers                                   | 2, 15 | 2, 5   | 8, 20 |
| (1)(C) approximate the value of irrational numbers                          | 8, 17 |        |       |
| (1)(D) express numbers in scientific notation, including negative exponents |       | 10, 13 | 3     |
| (d)(3)(A) use patterns to generate the laws of exponents and applies them   |       |        | 16    |

Figure 9. TEKS to TAAS alignment for objective 1.

as 37.5%. Likewise, one item in 2001 differs in alignment with the 2000 test. This constitutes a one out of four or 25% shift in content emphasis. Overall, we calculated the percent change in content alignment from 1999 to 2000 and then from 2000 to 2001 (see Figure 10).

| Obj      | 1     |       | 2     |       | 3     |       | 4     |       | 5     |       | 6     |       |

| % change | 25    | 0     | 0     | 0     | 0     | 0     | 50    | 25    | 37.5  | 12.5  | 62.5  | 37.5  | 0     | 0     |

Figure 10. Percent change in content alignment.

Our initial analysis showed that from 1999 to 2000 and 2000 to 2001, five of thirteen objectives were unchanged. For 1999-2000, an additional four objectives and for 2000-2001, an additional seven objectives showed under fifty percent changes, showing only four objectives in the first year and no objectives in the second year were altered more than fifty percent. We examined the variation in student performance to see if there was a simple relationship between student performance and variation in sampling (see Figure 11). There was not. This is an area that requires a more sophisticated form of analysis.

Our final analysis included an attempt to quantify difficulty in three ways: task consistency, task characteristics, and distractors. Within task consistency, we considered whether the content being tested was comparable between years. When the content topic was the same, we noted changes in task characteristics including number type, language use, single-step versus multi-step procedures, and the use of the money context. Distractor analysis was performed at the level of identifying answer choices that could easily be disregarded and/or common misconceptions. We identified the Objectives that a) appeared to have task consistency, were amenable to test preparation, and should produce relatively stable performance; b) objectives with varied difficulty in the items (harder or easier) across years and c) objectives with varied items

Figure 11. 10<sup>th</sup> grade student performance by objective.

and incommensurability in assessing difficulty. We compared our prediction and the item analysis provided by TEA of actual results of the percentage of students passing.

The results of our analyses showed the unreliability of making predictions based on our measures of item difficulty. We predicted that the 2000 test would be more difficult on all objectives based on our measures of difficulty except for Objectives 6 and 7 that we predicted would remain the same. According to the chart, we were correct for Objectives 5 and 9. Other results showed we were incorrect or only minimally correct for Objectives 10 and 13. Between 2000 and 2001 we had similar results. This is not surprising as test equating on TAAS is actually done using a Item Response Theory approach based in Rasch analysis. The difficulty levels are not publicly released.

Based on our analysis of TAAS for tenth graders, we found it difficult to draw any conclusions about student performance and improvement based on objective level analysis. These results suggest serious doubts about how teachers, after quantifying such results, are supposed to use this information to make a judgment about performance and thereby influence their instructional decision-making.

### Conclusions

Our research was focused on examining whether the data provided to teachers for instructional decision-making were valid for this purpose. We worked to extend

the analysis of the data in relation to the published test structure, and found that there were a number of problems in reconciling the results. The problem solving objectives obscured the underlying content dimensions making it difficult to judge the relative needs of students as regards topics. The variability in the student raw scores by objectives makes it unlikely that variations in student performance year to year represent real changes in student knowledge. A lack of trend data by objective suggests this variability is unlikely to represent systematic improvements in instruction. Finally, it did not appear that one could easily construct a content valid analysis of changes in difficulty in terms of topic selection, item characteristics or distractors.

In future work, we plan to continue to work to develop protocols that can validly guide teachers in undertaking content analyses of test results that can inform instructional decision-making. We hope to be able to link such analyses with the methodologies of test equating to determine whether there is a way to resolve the competing influences of psychometric test analysis and score preparation and content analyses. We encourage our colleagues in mathematics education to become similarly involved in close analysis of content dimensions of testing, to ensure that reform efforts at the curricular and instructional level are consistent with the messages given teachers from high stakes tests.

David Carrejo

The University of Texas in Austin  
carrejo@mail.utexas.edu

This paper reports on a study of high stakes testing in Texas as viewed from a ruling on the legality of the test for graduation. A summary of the Court ruling is analyzed as it relates to professional standards, empirical data and consequential systemic validity. An argument for increased empirical study of these accountability systems by content specialists is made if they are to be used as effectively as possible to improve classroom instruction.

High stakes testing is being used widely as a means to link standards to student outcomes within an accountability system designed to hold students, teachers and administrators responsible for systemic improvements in mathematics education. With the new Elementary and Secondary Education Act (ESEA) legislation and the Mathematics and Science Partnerships (MSP), this method of school reform is being extended nationally as a basis for receiving federal funds. It is essential for researchers in mathematics education to be observing and studying these evolving systems of education and ensuring that they are working to the benefit of students. This paper, two companion pieces (Confrey & Carrejo, 2002; Confrey & Makar, 2002) and a book, *Systemic Crossfire* (Confrey, in progress), present the results of two years of investigation of the Texas Assessment of Academic Skills (TAAS), its structure as a test, its content and its impact on classroom instruction. Our research is focused on the question, "can the results of high stakes testing inform instructional decisions?" rather than on the question "are the State scores going up?" Focusing on improvement in scores and the impact of tests on instruction are essential to ensure the accountability system is functioning as intended.

In previous work (Confrey, Bell & Carrejo, 2001), we argued that conflicting meanings of the terms standards and accountability can lead to "systemic crossfire" at the classroom level. We identified conflicts in the way accountability programs sought the improvement of standards (largely by monitoring rates of student passage on high stakes exams) while organizations of science and mathematics education scholars employed Standards as expressions of consensual conceptual targets for instruction. We examine how these tensions play out at the level of the instructional core as we conduct a form of research we call "implementation research" (see Confrey, Castro-Filhó & Wilhelm, 2000). Implementation research involves partnering with practitioners to improve student achievement and studying and documenting the catalysts and impediments to change using a model of systemic reform. Our cyclic model links

student outcomes to professional development to teacher knowledge and community to implementation of standards-based curriculum back to student outcomes (see Confrey & Makar, 2002).

In this set of papers, we concentrate on unpacking the use of the high stakes test first as they are embedded in the legal frameworks of the state where graduation is dependent on passing the tenth grade test; then as seen through content analyses protocols (Confrey & Carrejo, 2002), and finally, as viewed by teachers undertaking inquiry studies on their students' performances on the test (Confrey & Makar, 2002). To set the legal context, we present a summary of the case: *G. I. Forum vs. Texas Education Agency (TEA)*. We examine the ruling in relation to its interpretation of professional standards, empirical analysis, and its consequential systemic validity. Our findings offer lessons to other states as well as to Texas as they revise their examination system.

In 1999, nine students challenged the legality of the TAAS test as a requirement for graduation. Most had failed to pass the mathematics portion of the test, a sixty item multiple-choice test covering thirteen objectives. The TAAS exit test was given in 10<sup>th</sup> grade with up to six subsequent opportunities for students to pass parallel versions. The TAAS test is currently being replaced by the Texas Assessment of Knowledge and Skills (TAKS) which is designed to more fully measure the State's standards (Texas Essential Knowledge and Skills or TEKS). TAAS was heavily focused on arithmetic proficiency, and though touted as a higher cognitive test than its predecessor, TEAMS, it required little mathematics more advanced than single or double step solutions to word problems and interpretations of patterns in graphs and charts. More difficult items were added such as simple probability and a few literal equations. No calculators were permitted. The new test, TAKS, will however, be given in 9<sup>th</sup>, 10<sup>th</sup> and 11<sup>th</sup> grade with objectives covering algebra, geometry and problem solving and permit the use of the graphing calculator. Passing the 11<sup>th</sup> grade test will be required for graduation. Understanding TAAS, which has an eight year history and a court battle behind it is valuable in preparing the system what to expect from TAKS and in anticipating possible grounds for Court challenge. It can also inform accountability system development in other states.

The accountability system behind these tests remains quite stable. The raw score is converted into a scaled score, known currently as the Texas Learning Index (TLI) using a Rasch test equating methodology. Originally, in 1994, a raw score of 70% was set for passing by individual students, and subsequent tests have been equated to permit the Texas Education Agency to claim that one's learning index is an indicator of one's likelihood to be on track to pass the exit exam. To avoid low performing status, fifty percent of each subgroup greater than thirty students must pass the test, dropout rates must be lower than a given percent and the data must be of good quality across the district. This fifty percent rate has increased from 30 percent in 1996 as it is used a

means to drive the system towards consistent improvement. However one must keep in mind that student graduation remains consistently dependent on obtaining the TLI score of 70, so that while the system (teachers and administrators) is given relief early on, individual students are not.

After reviewing the one month of conflicting testimony in the fall of 1999, Judge Edward C. Prado of the Western Division of Texas (San Antonio) ruled, on January 7, 2000 that "The Court has determined that the use of the TAAS examination does not have an impermissible adverse impact on Texas's minority students and does not violate their right to due process of law" (p. 2, opinion). First of all, it is important to recognize that while the Judge ruled against the plaintiffs, he did acknowledge that from the results of the test, there is a clear indication of disparate impact. Disparate impact discrimination "outlaws unjustifiable practices that are facially race neutral but that fall more harshly on certain minorities." (p 4). His determination of disparate impact was based on data showing that "The evidence is undisputed that the Defendants knew, based on early projections, that a larger number of minorities would fail the TAAS than would white students. The Defendants projected that at a cutoff score of 70 percent; at least, 73percent of African Americans and 54 percent of Hispanic takers would fail the math portion of the test." (p. 5)

How can a judge rule that there is disparate impact but not rule against the test? This can only occur if the ruling limits the rights of the Courts to intercede, or the Judge determines that the test is not part of the problem that produces disparate impact but part of the solution to address it. Judge Prado did both. Drawing on three areas of law: desegregation, employment, and testing law, the Judge set the boundary conditions for the case.

Education is the particular responsibility of state governments. Moreover courts do not have the expertise, or the mandate of the electorate, that would justify unwarranted intrusion in curricular decisions. On the other hand, these considerations cannot be used to tie a court's hands when a state uses its considerate power impermissibly to disadvantage minority students (p. 2).

Judge Prado decided that the Courts could intercede to a limited extent because for the students the high school degree was deemed as a property right that was being denied to them. However, he also limited the Courts influence over curricular and instructional mandate in relation to setting objectives and monitoring instructional practices, and determined that on the whole, the test was soundly designed and seemed to be contributing to improvement rather than further discrimination. His ruling was based on a set of related findings that form his argument:

1. There was sufficient *notice* of the curricular objectives in question through widespread distribution of the Texas Essential Knowledge and Skills and the plans for implementing a graduation test.
2. The TAAS test was described as "solely an objective measurement of mastery"

and it “accomplishes what it sets out to accomplish, which is to provide an objective assessment of whether students have mastered a discrete set of skills and knowledge” (p. 24). In making this ruling, Judge Prado determined that the testing was necessary to overcome subjective teacher evaluations and inflated grades. By doing so, he *rejected correlations with grades as necessary evidence of test validity*. Further, he eliminated the need *demonstrating predictive validity* that is, correlating the test with future student success in college or work.

3. The process of *test construction as consistent with professional standards*. This process, summarized in Smisko, Twing, and Denny (2000) involves the identification of a set of curricular objectives to be tested, test objectives, writing items by experts (including teachers, test writers), reviewing items, field-testing and further review. He wrote, “... there was no testimony demonstrating that Texas has rejected current academic standards in designing its educational system. Educators and test-designers testified that the design and use of the test was within accepted norms”(p. 29).
4. The pass rate was viewed as set in a manner consistent with professional standards and constituted the right of the state to demand that students’ demonstrate *70% test mastery of the declared material*. Furthermore, he accepted the Rasch model of test equating which focuses on item difficulty parameters but not on item weighting as an appropriate way to adjust scores from year to year... Thus, the pass rate could vary relative to raw scores as indexed by Texas Learning Index score transformations.
5. The multiple administrations of the exit test were considered to be a valid way to avoid the stipulation that graduation should not be dependent on a single test score. The conjunctive requirements of passing TAAS, and accumulating course credits were also viewed by the Judge as *avoiding reliance on a single test score*.
6. The system of *remediation* was considered adequate as a means to provide students sufficient assistance in overcoming test failure. Judge Prado explicitly *validated test driven instruction* as a legitimate professional practice. On this, he wrote, “The Plaintiffs introduced evidence that, in attempting to ensure that minority students passed the TAAS test, the TEA was limiting their education to the barest elements. The Court finds that the question of whether the education of minority students is being limited by TAAS- directed instruction is not a proper subject for its review. The State of Texas has determined that a set of knowledge and skills must be taught and learned in State schools. The State mandates no more than these “essential” items. Test-driven instruction undeniably helps to accomplish this goal. It is not within the Court’s power to alter or broaden the curricular decisions made by the State” (p. 26).

7. "The State of Texas... has designed the TAAS *accountability system* to reflect an insistence on standards and educational policies that are uniform from school to school" (p. 5). This uniformity in relation to essential skills and knowledge required for graduation helped the Court decide the test was fair, despite disparities.
8. He viewed the process of notice and test construction as a form of *curricular validity* and a surrogate to *instructional validity*. On this, he wrote, "in reviewing items, educators are instructed to consider the following issues: relevancy of the item, difficulty range, clarity of the item, correctness of the keyed answer choice, and plausibility of distracters. ... Reviewers are asked to assess whether or not each item on the TAAS exam covers information that was sufficiently taught in the classroom by the time of the test administration"(p. 9). This ruling relies heavily on the assumption that the reviewers of the tests know what is actually taught in the various schools around the state.
9. He accepted the position that *items showing diverse impact* could be retained on the test if it is a "fair measure of its corresponding state objectives *for all students*, and is free of offensive language and concepts that may differentially disadvantage minority students" from the testimony of S. Philips, cited p. 10.
10. He was convinced that the *empirical evidence supported progress* and rejected testimony concerning the increasing dropout rates particularly at grade nine. The evidence showed decreasing gaps between minorities and Whites on TAAS scores, showed statewide progress on the National Assessment of Educational Progress, and showed increases in enrollments in higher level courses and Advanced Placement exams. He wrote, "... the Court has had to weigh what appears to be a significant discrepancy in pass scores on the TAAS test with the overwhelming evidence that the discrepancy is rapidly improving and that the lot of Texas's minority students, at least as demonstrated by academic achievement, while far from perfect, is better than that of minority students in other parts of the country and appears to be getting better" (p. 4).
11. His ruling was also based on his claim that the plaintiffs had provided *no better alternative*. One almost sees in his ruling a lament that more effective systems of education are not in place. He wrote, "Ultimately, the resolution of this case turns not on the relative validity of the parties' views on education but on the State's right to pursue educational policies that it legitimately believes are in the best interests of Texas students. The Plaintiffs were able to show that the policies are debated and debatable among learned people. The Plaintiffs demonstrated that the policies have had an initial and substantial adverse impact on minority students. The Plaintiffs demonstrated that the policies are not perfect. However, the Plaintiffs failed to prove that the policies are unconstitutional, that the adverse

impact is avoidable or more significant than the concomitant *positive* impact, or that other approaches would meet the State's articulated legitimate goals. In the absence of such proof, the State must be allowed to design an educational system that it believes best meets the need of its citizens" (p. 7).

The impact of the case on the testing climate in the state has been to increase the adversarial relationships between those who support and oppose the tests, rather than to encourage the development of improvements to bridge that gap. For example, perhaps due to the success of the legal case, changes have been made to the TAKS testing system abandoning plans to use subject specific End of Course exams. We believe the action is designed to create a single comprehensive exam as a graduation requirement, thus aligning it more closely with the TAAS system and lessening its vulnerability to legal action. Having survived a legal challenge, TAAS has become a testing blueprint. It is essential that researchers in mathematics education are aware of the legal conditions surrounding high stakes testing and that we consider both theoretically and empirically the impact of these conditions on classroom practice, especially in relation to the quality of mathematical content. Our discussion of these issues is placed in the context of a critique of the ruling as it is related to three categories of use of high stakes data. These are:

1. Questioning whether the ruling is consistent with the professional standards of testing
2. Reporting on the contested data trends that were used to establish overall system improvement, and
3. Raising the neglect of consequential systemic validity as a weakness in the ruling.

The first category permits us to address more deeply the adequacy of the Prado ruling as regards points 1, 5 and 8 of his argument. The second focuses further discussion on point 10 and the third category of critique permits reexamination of points 6, 7 and 9 in the ruling. The second paper builds on the second type of critique and relates it to the limited adequacy of the data to guide instructional decision-making. The third further explores what is possible in relation to consequential systemic validity. We hope to propose a revised system of accountability and its links to the instructional core in subsequent work.

### **Professional Standards of Testing**

In a relatively recent publication, *High Stakes: Testing for Tracking, Promotion and Graduation* (Heubert & Hauser, 1999), the Board on Testing and Assessment of the National Research Council discussed their interpretation of professional standards for testing. Using the primary constructs of reliability, validity and fairness, they emphasized the need for these powerful instruments of policy and accountability to be used carefully and wisely. They warn, "When tests are used in ways that meet techni-

cal, legal and educational standards, students' scores provide important information that, combined with information from other sources, can promote both learning and equal opportunity. On the other hand, they can reinforce and legitimate biases and inequalities that persist in American society and its schools. Used improperly, tests can have serious negative consequences—for individuals, particular groups, and society, as a whole" (p. 26).

A major message of the book is that "concern is also reflected in current psychometric standards, which recommend that a decision that will have a major impact on a test taker should not be made solely or automatically on the basis of a single test score, and that other relevant information about the student's knowledge and skills should also be taken into account (American Educational Research Association, American Psychological Association, & National Council on Measurement in Education, 1985; American Educational Research Association, et al., 1998, Standard 8.12)" The question is "does the opportunity to retake the TAAS test up to six times constitute an acceptable means to address this requirement?" According to Judge Prado, it does. Our reading of the testing standards indicates that multiple opportunities to take a test designed under identical specifications do not meet this standard. While repeated administrations might improve students' chances of eliminating the results of random error in their score, we interpret the standard to be addressing the need for qualitatively different forms of measurement. The legal ruling accepted empirical evidence of subsequent passes as sufficient evidence that adequate remediation had been provided and hence that multiple testing opportunities met the professional standard of non-reliance on a single score. Future statements of professional standards will need to address this question more explicitly.

The second professional standard compromised by the ruling involves the decision to rely on curricular validity rather than on instructional validity. The authors of *High Stakes: Testing for Tracking, Promotion and Graduation* state that "It is neither straightforward nor inexpensive to measure the content of actual instruction (Popham and Lindheim, 1981). As a result, there is little evidence to suggest that exit exams in current use have been validated properly against the defined curriculum and actual instruction; rather it appears that many states have not taken adequate steps to validate their assessment instruments and that proper studies would reveal important weaknesses (Stake, 1998). Our classroom research suggests that many urban students have been inadequately prepared on multiplication, division and ratio reasoning, in part, perhaps due to over reliance on calculators which were prohibited in TAAS testing. A failure to consider instructional validity compromises standards of fairness and leads to deficit thinking about certain student groups.

### **Challenges to Empirical Data**

The second challenge to the ruling has been in relation to empirical data. Below, one sees the state of Texas's data that the students in Texas are improving in part as a

result of the accountability system when the percent of students equaling or exceeding a TLI of 70 is graphed over time (see Figure 1).

In this graph, one notes that both the overall scores on the test are improving and the gap among Whites, African-Americans and Hispanics is decreasing. The graphs constant improvement and narrowing of disaggregated trend lines are cause for optimism. The fact that they are not linked to drop out rates forces one to ask whether the students are being lost in the process. Contention over drop out rates is common in the state (House Research Organization, 1999). References to improvements in NAEP and AP enrollments can be found elsewhere.

However, it is instructive to also examine same data by the mean score on the TLI rather than the percent passing (see Figure 2). This score will be affected by the performance of not just those students who were successful but also by those who scored poorly on the test.

These data are somewhat less promising with lower slopes and less narrowing of the gap. These results suggest that either the means vary over time less than the percentage pass as a function of the test equating methodology or that the improved successes of the students' passing the test are not accompanied by improved performance by students at the other end of the spectrum. Another possible implication of these data is that there is an excessive amount of effort by schools in improving their passing rates by working disproportionately with students who are near the cut-point known as the "bubble kids."

Figure 1. Percent passing over time.

Figure 2. Average TLI over time.

A third set of data over time relates to the raw scores of students on the test. As shown by the next graph, the raw scores of students on TAAS exit test have dropped precipitously between 2000 and 2001 (see Figure 3). For the last two years, the average score on TAAS by students is 43.2 of 60 items. Keep in mind on a multiple choice test with four or five distracters; one can expect a score of 12-15 correct by chance alone. One immediately wonders if the loss in the mean in the raw scores is experienced by all students or only those near the bottom.

By examining a graph of the raw score corresponding to a TLI of 70, or a pass on the test for an individual, one can see that the students passing the test are scoring lower (see Figure 4).

We present a listing of the means and standard deviations by the whole group and subgroups to permit one to examine trends in the distributions as well as the means (see Figure 5).

We recommend an emphasis on the examination of distributions of scores rather than solely percent pass as a fundamental tenet of our research protocols. Only by doing so can one begin to determine if students in all performance levels are adequately served.

Figure 3. Average raw score over time.

Figure 4. Raw score corresponding to a TLI of 70 over time.

|            | Year |      |      |      |      |      |      |      |
|------------|------|------|------|------|------|------|------|------|
| Ethnicity  | 1994 | 1995 | 1996 | 1997 | 1998 | 1999 | 2000 | 2001 |
| All-Mean   | 41.9 | 42.9 | 43.6 | 45.4 | 46.2 | 48.9 | 49.2 | 43.5 |
| All-SD     | 12.3 | 12.4 | 11.8 | 11.6 | 10.9 | 9.8  | 9    | 10.6 |
| AA-Mean    | 35.3 | 36.3 | 37.7 | 40   | 41.2 | 44.4 | 44.9 | 38.4 |
| AA-SD      | 12.2 | 12.5 | 12.4 | 12.5 | 11.6 | 10.9 | 10.1 | 10.7 |
| HISP-Mean  | 37.7 | 38.4 | 40   | 41.7 | 43.1 | 46.4 | 46.9 | 40.4 |
| HISP-SD    | 12.4 | 12.5 | 12.2 | 12.3 | 11.5 | 10.6 | 9.6  | 10.7 |
| WHITE-Mean | 45.5 | 46.7 | 46.8 | 48.8 | 49.2 | 51.4 | 51.4 | 46.6 |
| WHITE-SD   | 10.9 | 10.7 | 10.3 | 9.7  | 9.3  | 8.1  | 7.4  | 9.4  |

Figure 5. Means and standard deviations by group and subgroups.

Reconciling the data between raw scores and TLI demands empirical tests. According to the Texas Education

Agency, the test items are becoming more difficult as the test is increasingly aligned with the state standards, TEKS. We have tried to examine this question using content analyses as reported in the second paper. We have also tried to examine the difficulty levels by Rasch analysis but these data are not public. Regardless of whether the test equating is done correctly, it is of critical importance that teachers are provided their classes data in the form of the raw scores disaggregated by objective, and an item analysis of the test. This is the data that teachers as a group use to adjust their classroom practices. In our second paper, we use content analysis and an examination of the objectives over time to see if these data can be useful in informing classroom practice. In subsequent work, we plan to undertake statistical analysis of the test equating process in order to link it to an examination of the test by objective. We are concerned to understand better how the psychometrics of test equating may be affecting the construct validity of the links between TEKS and test objectives and items.

### Consequential Systemic Validity

The final analysis we offer is that the Court ruling seems to be very naïve as regards the impact on the testing system on the system itself. This is due to a tendency to view the education system as a production system rather than as a feedback system. We point to four ways in which this can lead to serious problems in school level practices.

1. The results of testing can be used to short circuit the curriculum and lead to teaching to the test As stated in *High Stakes: Testing for Tracking, Promotion and Graduation*, "A comparison of low- and high-stakes state testing programs found that, as the stakes of testing increase, "there is a point at which district strategies take on the flavor of a single-minded devotion to specific, almost 'game-like' ways to increase the test scores" (Wilson & Corbett, 1991:36 p. 173). Finding the line between reasonable test familiarity and excessive test preparation requires one to examine the question empirically.

2. The accountability system does not hold teachers accountable for all students, and hence over time, students in the bottom 30% of the achievement group may fail to be adequately served. A longitudinal empirical study of the consequential validity of the test for this group would permit one to ascertain this impact, but difficult to do as the privacy features of the data sets tend to make it difficult to examine. A similar argument can be made for dropouts who may leave the system anticipating or fearing failure (Haney, 2000). A closed model linking test performance to dropouts as a population model needs to be devised to monitor this issue.
3. Teachers are not provided with sufficient training in statistics nor are they provided with enough opportunities to access the data for study. Our third paper reports on efforts to use the test results in this inquiry based manner.
4. There is a perception that legal safety is increased by minimizing empirical investigation. Rather by accepting that consequential systemic validity must be investigated empirically and scientifically, we can increase the likelihood that the system will mature rather than polarize.

### Conclusions

This paper and its companion pieces raise questions as to how well the accountability system in Texas is currently acting as effectively as possible as a useful guide to improving classroom practice. It argues that mathematics education researchers must become more deeply involved in examining the ways in which test construction and analysis can be informed by a deeper knowledge of content. Further, it suggests that serious questions of fairness may be neglected without more informed and empirical study of the links between testing and classroom practice.

# **THE IMPACT OF AUTHORITY AND REFLECTION ON TEACHERS' USE OF OPEN-ENDED ASSESSMENT ITEMS**

Wendy B. Sanchez  
Kennesaw State University  
wsanchez@kennesaw.edu

Nicole F. Ice  
rnice@mindspring.com

Research has shown that mathematics teachers' current assessment practices are not consistent with recommendations in the mathematics education reform literature. One recommended strategy is the use of open-ended assessment items. This paper reports the findings of two studies designed to investigate factors that facilitated or impeded teachers' use of such items. Two middle grades and three secondary mathematics teachers who had participated in professional development projects designed to expand their understanding of the purposes and uses of assessment, as well as to change their instructional and assessment practices, were participants in the studies. Findings from the studies include that teachers' orientations to authority affected their use of open-ended assessment items, as did the focus and extent of the teachers' reflective thinking.

## **Introduction**

The teachers in the studies participated in professional development projects designed to help them meet mandated student assessment requirements. The mandate was that at least 20% of the items on all classroom tests must require higher-order thinking on the part of students. County policymakers expected teachers to change their instructional methods to incorporate more reform-oriented instruction when faced with a requirement to do so with their classroom assessments. The professional development projects provided an analysis of the rationale for and characteristics of reform-oriented assessment practices, as well as the development of strategies for writing open-ended assessment items and practice in scoring student responses to such items. The projects resulted in open-ended item banks created by the teachers which they could use to meet the assessment mandate. The findings of prior research have pointed to such factors as resources, time, and knowledge as impediments to teachers' success with implementing alternative assessment strategies (e.g., Nash, 1993; Senk, Beckmann, & Thompson, 1997). The professional development projects addressed these factors in numerous ways, which included providing an open-ended item bank and practice in scoring student responses to open-ended items. Once attempts were made to control for the impeding factors, it was possible to investigate the more cognitive factors that affected the teachers' use of open-ended assessment items.

## **Theoretical Perspectives**

Prior literature indicates a relationship between teachers' orientation to authority and their instructional practice (Thompson, 1992). Therefore it was reasonable to

expect that orientation to authority would also affect teachers' assessment practices. The teachers' orientation to authority was investigated using epistemological development models (Baxter Magolda, 1992; Belenky, Clinchy, Goldberger, & Tarule, 1986; King & Kitchener, 1994; Perry, 1970/1999). These models imply a continuum from a dependence on authority for knowledge to a development and evaluation of knowledge in context.

During the studies it became evident that the teachers differed in the focus and extent of their reflection. Thus, a theoretical perspective on reflective thinking was necessary. Reflection was viewed from Dewey's perspective. Dewey (1933) defined *reflective thinking*, as the "active, persistent, and careful consideration of any belief or supposed form of knowledge in the light of the grounds that support it and the further conclusions to which it tends" (p. 9). The process of reflective thinking occurs in two phases. First, a person enters "a state of doubt, hesitation, perplexity, mental difficulty, in which thinking originates" (p. 12). The person recognizes something as problematic. What follows is "an act of searching, hunting, inquiring, to find material that will resolve the doubt, settle and dispose of the perplexity" (p. 12). The demand for a conclusion to a problem is the definitive characteristic of reflective thinking. Dewey stated that there are occasions in which something is considered problematic and a suggestion for resolution emerges, and yet reflective thinking does not occur. In these instances the person is not "sufficiently *critical* about the ideas that occur to him" (p. 16). The person takes the first answer or solution that occurs to her or him, and thus does not become completely immersed in the careful search for a resolution.

### Methodology

The participants in the studies were two middle grades mathematics teachers (Sue and Leah) and three secondary mathematics teachers (Todd, Robin, and Keith), all five of whom participated in the professional development projects previously described. The qualitative data were collected during extensive classroom observations and from interviews, surveys, and artifacts. Sue and Leah were each observed teaching in an eighth-grade Algebra I class. Todd was observed teaching Algebra Concepts (a traditional Algebra I course taught over two years) and Algebra II, Robin teaching Algebra I and Calculus, and Keith teaching Algebra II and Pre-calculus.

There were two phases of inductive data analysis (Patton, 1990). The first phase consisted of a descriptive analysis in order to answer basic questions about the teachers' practices. The second phase consisted of analyzing the data with an emphasis toward interpretation using the theoretical orientations.

### Findings

Beliefs, authority, reflection, knowledge, and constraints emerged from the two studies as factors that influenced teachers' use of open-ended assessment items. The present paper addresses two of these factors, authority and reflection. The five teach-

ers varied in what they used as sources of authority for their teaching practices. The teachers also varied in the focus and extent of their reflective thinking. The focus of the teachers' reflective thinking refers to the issues that they found problematic. The extent of their reflection refers to the degree to which they were sufficiently critical in their search for resolution with respect to the issues they found problematic. Both authority and reflection are discussed below for each participant along with their impact on the teachers' use of open-ended items.

### **Sue**

Sue's main source of authority for her teaching was the textbook. She progressed through the textbook, page by page, section by section, chapter by chapter. She presented the textbook examples and then assigned textbook exercises. She told the students that "The most important thing you are going to learn is in this textbook" (Ice, Observation). Sue's dependence on the textbook for the structure and content of her teaching was obvious when she questioned the sequencing of topics in the textbook but followed the given order anyway. The textbook included the topic of the mean of a set of numbers in the section of chapter 2 about dividing rational numbers. Sue said that it was "a weird place to put mean" (Comment to Ice, Observation), but she still taught the lesson according to the order and examples given in the textbook. During instruction, Sue focused on the procedures that were presented in the textbook. Since most of the text's items were procedural, that is what Sue's instruction reflected. Thus the authority of the textbook impeded Sue's use of open-ended items during instruction. Other sources of authority for Sue included high school mathematics teachers and courses and the county school system. These sources of authority facilitated her use of open-ended items because she believed her students would encounter those types of items in high school and because she wanted to meet the county assessment mandate. However, Sue only used open-ended items on quizzes and tests and only for the purpose of assigning grades. When asked if she would make any changes in her teaching as a result of using the items, Sue replied, "No" (Ice, Interview 3).

Issues that Sue found problematic were student attendance, student course level, and lack of student learning. She believed that absences caused students to miss a large amount of mathematical content and that they were unwilling to make the effort to come in for extra instruction. To Sue, students' absences accounted for much of their misunderstanding. Sue determined that the students needed to be more diligent in their efforts to attend class. She also believed that it was problematic that too many students were taking Algebra I in the seventh grade and Geometry in the eighth grade. In addition, she thought too many students were taking Algebra I in eighth grade. She believed that the students' level of maturity was not sufficient for them to be successful in those classes at those grade levels. She believed that even though those students could pass Algebra I and Geometry in the middle grades, their lack of maturity would keep them from learning the material as well as they should, and thus the students

would encounter considerable difficulty in the mathematics classes in high school. As a result of her belief and her position as department head, Sue decided to make an effort to reduce the number of seventh- and eighth-graders taking Algebra I and Geometry. Finally, lack of student learning, as evidenced by low grades on quizzes and tests, was also problematic for Sue. She thought that maturity was the main factor that contributed to a lack of student learning. She believed that the students were just not ready to make the kind of effort that was required to be successful in Algebra I. Also, she believed that they did not want to spend time interpreting both traditional and open-ended items correctly, did not have the patience to read them thoroughly, and did not take the class seriously. Sue also believed that the students were not motivated, that their parents pushed them into Algebra I when they were not really ready to handle the course, and that the students' prior instruction in Pre-Algebra did not sufficiently instill the basic skills such as operations with integers and solving simple equations. Sue said she would continue not being easy on the students and demanding that they raise their level of effort in her class. Because Sue's most problematic issues were students' attendance and level of coursework, factors that were not under her control, they did not appear to have the ability to impact her use of open-ended items in any significant way. The issue of lack of student learning did appear to have the ability to impact Sue's instructional and assessment practices, however, her ability to explain the students' lack of learning in terms of student shortcomings inhibited her reflection.

### **Todd**

Todd's sources of authority included the textbook, the leaders of the professional development projects, the county school system, and other teachers in his school, especially his mentor teacher who also participated in the professional development projects. Todd was relatively new to the teaching profession and therefore did not consider himself to be an authority on teaching. He used the textbook as a prescription for teaching. He used a lot of "they" language when he talked about how and what he taught. When asked if he planned to address a particular topic, he would respond with something such as "They don't get into that," they meaning the authors of the textbook. When asked how he would teach logarithms (a topic he had not yet taught), he responded, "I don't know necessarily what the book or the curriculum wants me to teach" (Sanchez, Interview 7). Todd felt a responsibility to follow the county assessment mandate. Because Todd used open-ended items on his tests and it was discussed during the professional development that assessment should be aligned with instruction, he also used open-ended items during instruction. He also claimed to use open-ended items because they require students to think on a higher-level. Todd used open-ended items often, both during instruction and on quizzes and tests. However, the way Todd used open-ended items minimized the potential for fostering higher-level thinking in his students. He often gave open-ended items as group work and assigned a completion grade. He was not willing "to waste more than a couple minutes

on a problem” (Sanchez, Interview 3). Although he assigned open-ended items often, during class he did not spend much time on those items and often “glossed over” them. Although the textbook did not facilitate Todd’s use of open-ended items, his other sources for authority did support his use of those items, albeit in a superficial way.

Issues that Todd found problematic were students’ prerequisite mathematical knowledge, teacher expectations, students’ perception of his mathematical knowledge, and lack of student motivation. Todd was concerned that students did not have a mastery of the basic mathematical skills that they should have prior to entering his class. In order to address this issue, Todd focused his teaching on basic skills and procedures. Although he assigned open-ended items, his concern about basic skills limited the time he was willing to spend addressing students’ thinking about those items. Todd found it problematic that many teachers accepted student mediocrity and did not have high expectations for student learning. Thus, he felt it was important to ask questions that challenged students, and the use of open-ended items helped him meet that goal. Todd wanted to be a mathematical authority in his classroom and found it problematic if his students perceived that he was mathematically unsure. Open-ended items, by nature, introduce unpredictability in the classroom. Although this unpredictability did not inhibit Todd from assigning open-ended items, it did limit his willingness to explore students’ thinking about the items and caused him to quickly escape situations that made him feel mathematically uncertain. Finally, Todd found students’ lack of motivation to be problematic. He used open-ended items to address this issue by assigning them as a warm-up or group activity for which he gave either a completion grade or bonus points. Thus, Todd’s use of open-ended items was facilitated by his desire to address motivation, but again, the use was superficial.

### Leah

Leah made instructional decisions based on her teaching experience and what felt appropriate to her. She had confidence in her expertise as a teacher and relied on that expertise to make decisions. She decided on her own explanations and examples to use during instruction and sometimes did not present material in the same order as the textbook. She used the textbook for student homework assignments. Leah’s belief in herself as an authority was obvious from the decisions she made regarding her teaching. For example, when she felt it was best for her students to spend additional time covering basic skills, she did so, even though she commented that other teachers covered the same material more quickly. Also, she chose not to use the open-ended item scoring rubric developed during the professional development project because it did not fit into her grading scheme. Instead, she developed her own way of scoring student responses that was more appropriate for her situation. Leah used open-ended items on tests, as was mandated by the county. She did not, however, integrate open-ended items into her instructional routine even though she considered herself an authority for instructional decisions. Perhaps since Leah’s main source for authority

for instructional decisions, her prior teaching experiences, did not include the use of open-ended items during instruction, she did not include open-ended items as part of her instructional approach. Additional sources of authority for Leah were the NCTM and the county school system. The NCTM facilitated Leah's use of open-ended items on her tests because she believed they helped her approach NCTM's vision for assessment in mathematics. Similar to Sue, Leah used the items to meet the county assessment mandate.

Leah found the ability to change her teaching practice problematic, as well as low student test grades and student responses to open-ended items. Leah seemed to be searching for something to help improve her teaching. She kept adding discrete items to her repertoire of instructional and assessment techniques. Even though she considered herself a learner, Leah claimed it was difficult to change her teaching practices:

I think it takes a long time and a lot of hard work. It cannot be done in a very short period of time. I think we have to try one or two things a year and then make a change maybe over a 10-year period. I think it takes a long time. (Ice, Interview 1)

Leah's motivation for change in her teaching was grounded in her ability to "step outside [herself] and see some things that are not the best" (Ice, Interview 2) and resulted from her analysis of her teaching and her efforts to find better ways to help students learn mathematics. Leah found change difficult and the way she dealt with the difficulty was to add small changes in over extended periods of time. Thus, the changes she incorporated with respect to assessment were limited to adding open-ended items to her tests.

Leah searched for reasons to determine why students made low grades on her tests. She concluded that there were several actions that she and the students could take to help them improve their grades. With respect to open-ended items, Leah maintained that the items were new to the students and that they would become better at responding to open-ended items with practice. Also, the day before the chapter 2 test, she reviewed with her students how to answer four open-ended items similar to ones that were on the test. In order to learn their mathematics better, Leah suggested to the students that they acquire better study habits as well as habits that would improve their ability to learn from her instruction (such as taking notes better, less talking in class), that they put forth more effort to learn, and that they stop being so careless and making mistakes in their work. These suggestions, along with encouraging the students to find someone outside of class (a parent, sibling, friend, or tutor) to help them learn their algebra, were ways in which Leah believed the students could improve their grades. Her conclusions led her to reduce the number of open-ended items on her tests because she was going beyond the 20% mandate.

Leah was surprised, and thus found it problematic, that students could not respond to open-ended items as well as she thought they should be able to. One reason for their

poor performance was that, as mentioned above, she felt that the students did not know their mathematics well enough to appropriately respond to the items. Further, Leah believed that the students struggled with the details of open-ended items and that they did not have the ability to pay attention to so many details in one item. The last reason that she believed caused the students to respond poorly to open-ended items was that they were not clear about the directions, wording, or intent of some of the items, and thus interpreted them incorrectly. Along with the suggestions to help students improve their grades, Leah tried to help students respond better to open-ended items by sometimes giving hints, and she made an effort to select open-ended items that she believed were worded more clearly.

### **Robin**

Robin made decisions about teaching based on her own teaching goals and experiences. One of those goals was that she should finish the county curriculum. This goal may seem to be related to a reliance on external authority, but more likely it was related to the fact that Robin helped create the curriculum and felt ownership of it. The fact that Robin did not always follow the assessment mandate illustrated her willingness to deviate from the authority of the county school system. She said,

I feel a responsibility to myself more than I do to any of those other outside groups or people or anything. Because I'm...gonna do what I need to do in the classroom because of why I think I'm here. Not because [the] county tells me to cover XYZ....But because, you know, I'm a serious committed person to teaching, and I'm going to do it the way that I feel it needs to be done. (Sanchez, Interview 4).

Robin's commitment to the curriculum sometimes overrode her commitment to open-ended assessment, but when she did use open-ended items, she used them to support higher-level thinking on the part of her students and to inform her teaching. She did not use open-ended items because she was supposed to; she used them because they helped her reach her broader educational goals.

Robin found the issue of time to be problematic. She also viewed her instructional and assessment practices as problematic. Robin's commitment to finishing the county curriculum inhibited her use of open-ended items because she was hesitant to use valuable class time to investigate student thinking. She also recognized that it took students longer to respond to open-ended items than more skill-based items. She was only occasionally willing to take the time to incorporate open-ended items into her instruction. Robin also found her instructional practices problematic in the sense that she was always searching for better ways to increase student mathematical understanding. If a student approached a problem in a way that made more conceptual sense to Robin than the way she had presented it, then she said she would adopt the student's approach the next time she taught the topic. She viewed her teaching as open

to scrutiny from herself and others and accepted that other methods could be better than the one she originally used. While Robin used open-ended items sparingly during instruction, and more often on tests and quizzes, she used the student responses to those items to meaningfully inform her instruction. Finally, Robin viewed assessment as problematic because she realized that it was possible for students to have a conceptual understanding of mathematics while lacking precision in carrying out computations. These students, according to Robin, are unfairly assessed by traditional means in which students are required to perform rote procedures. Thus, Robin used open-ended items on quizzes and tests to provide opportunities for students to demonstrate their conceptual understanding.

### **Keith**

Keith's teaching was mostly unaffected by the authority of the county school system and the textbook. He based his teaching decisions on a variety of sources. He used the county curriculum "as just kind of an outline.... It's my responsibility to decide what it is that the students learn" (Sanchez, Interview 4). When asked if he used the textbook to decide how to teach a particular topic, Keith responded, "Yes, because it's just another point of view from mine. If I know of better ways to present the topic, I usually present them my own way" (Sanchez, Interview 4). Keith used open-ended items during instruction as a way to find out what students knew. In his Algebra II class, Keith presented an open-ended item about systems of linear equations, to which students were unable to provide satisfactory responses. What followed was a discussion that led to increased student understanding of solving systems of linear equations. Because Keith used this item, he was able to determine that the students lacked some understanding of solving systems of linear equations and as a result used the information to make an appropriate instructional decision.

Keith found the issues of student mathematical thinking, instruction, and assessment as problematic. According to Keith, students think about and learn mathematics differently. He recognized that students can know and understand mathematics differently than he does. He valued student approaches to solving problems in his classroom by having students explain their reasoning or by presenting more than one method if students were not comfortable with his original method. Open-ended items allowed students to approach problem-solving in a way that was consistent with how they understood the mathematics. Keith therefore embraced the use of open-ended items as a window into his students' thinking. Because he believed that students learn mathematics in different ways, Keith found instruction particularly problematic because one approach would not necessarily reach all students. Therefore, Keith used open-ended items as part of his instructional practice so he could identify student thinking and modify his instruction accordingly. Keith found that traditional assessment, in which students are asked to generate specific responses, does not allow students to demonstrate their own mathematical knowledge. Keith's use of open-ended assessment items helped alleviate this aspect of assessment that he viewed as problematic.

### Discussion

The teachers' sources of authority impacted their use of open-ended items in the sense that if the teacher relied on an authority who supported the use of those items then the teachers tended to use them. Some sources of authority promoted the use of open-ended items (NCTM, the county school system, the professional development leaders) while others hindered the use of those items (the textbook). We did not find, however, that relying on a source of authority which supported the use of open-ended assessment resulted in a use of the items that is consistent with the reform efforts in mathematics education. In other words, authority might play a role in getting teachers to use open-ended items but it might not be able to affect how the teachers use them.

Sue, Todd, and Leah each identified aspects of their teaching practice as problematic and searched for and determined suggestions for resolution. However, it appeared that, as Dewey (1933) described, the teachers were not sufficiently critical about the issues and seemed to accept somewhat superficial solutions to their problems. Thus, according to Dewey, these teachers did not engage in reflective thinking. Since the teachers did not appear ready or willing to engage in reflective thinking about their problematic issues, they did not reach the stage of carefully searching for a resolution. Thus, open-ended items were not considered helpful to the resolution process. In contrast, Robin and Keith engaged in reflective thinking as a way to address the issues they found problematic. Keith explained,

Before I got involved with alternative assessment, it was like, I don't know what to do—something is missing. And now I have something I can grab onto. I've always been somebody who likes to ask questions [while teaching]. It is just that I didn't always have, I don't think, the framework that I needed to ask a good question, thinking about possible responses and thinking about how you would determine if those were good responses. Now I'm thinking about that all of the time. Not only do I just reflect about what I have taught, but I think more about it before I teach. (Sanchez, Interview 7)

Both Robin and Keith used open-ended items to better understand their students' thinking and used the information they gleaned about students' thinking to inform their instruction.

Not only was there a difference between the extent of reflection among the teachers, but the focus of their reflection—the problematic issues—was fundamentally different. Sue and Todd found issues such as attendance, motivation, and prior knowledge to be problematic. Although these issues can affect classroom dynamics in significant ways, they are largely out of the teachers' control. These three teachers indicated that poor student performance is due to characteristics of the students. In contrast, Leah, Robin, and Keith found issues such as student responses to open-ended items, low test grades, instruction, assessment, and students' mathematical thinking as problematic.

Not only are these issues more in the domain of issues that teachers can control or impact, but they are also the constructs that are epistemologically and pedagogically central to teaching, namely instruction, learning, and assessment. While Leah did not engage in reflective thinking as defined by Dewey, Robin and Keith did engage in such thinking. These findings suggest that teachers who engage in reflective thinking about constructs that are central to teaching tended to use open-ended items in a way that was consistent with the intended purpose of those items—to inform teachers about students' mathematical thinking in order to guide instruction and assess understanding.

### Conclusions and Implications

Teachers' orientations to authority impacted the use of open-ended items. Some sources of authority hindered teachers' use of open-ended items while other sources facilitated such use. However, a reliance on sources of authority that facilitated item use did not necessarily promote teachers' meaningful use of those items. Thus, while authority can lead teachers to use open-ended assessment items, it does not guarantee that teachers can use such items in ways to promote students' deeper understanding of mathematics.

The focus and extent of teachers' reflective thinking also impacted the use of open-ended items. Teachers who engaged in reflective thinking about issues that were within their realm of control and were central to the practice of teaching were more likely to use open-ended items in a way that helped promote students' mathematical understanding.

The findings from these studies suggest that preservice education and professional development programs should help teachers move beyond just using alternative assessment strategies, such as open-ended items, and help them use student responses to make instructional decisions that will promote students' deeper understanding of mathematics. Programs should provide teachers with opportunities to develop specific strategies for using information gained from alternative assessment techniques to inform their teaching. If professional development programs aim to help teachers move more towards reform-oriented practice, we suggest that those programs go beyond teaching specific techniques for instruction and assessment and challenge the fundamental assumptions that underlie teaching. These programs need to provide teachers a context for reflection in order to enable them to view teaching as problematic. Viewing teaching as problematic is the precursor to engaging in reflective thinking about teaching. Teachers need to be provided with opportunities to frame teaching as a problematic activity as well as to engage in the process of searching for resolution. After these programs are implemented, future research could investigate their ability to impact teachers' practice.

This research, briefly summarized, was designed to document the teaching practices of a sample of fourth grade mathematics teachers from across the state of New Jersey, over the course of a two-year period. A major part of the study investigated the teachers' reactions to a new statewide testing program. We were particularly interested in how they perceived the new test to be impacting their teaching, in the context of what was actually happening in their everyday instruction. To this end, the research methodology incorporated both a sample survey and interviews, and direct observation with post-observation interviews. This particular report focuses on the classroom observation and interview components of the study. The codes used to assess classroom practice were based upon the work of other researchers who have developed coding systems for use in analyzing classroom practice. Briefly, the data suggests that the teachers have adopted new strategies in response to the state test but are not changing their basic approach to teaching mathematics.

**Introduction**

In this research<sup>1</sup>, we were interested in learning more about how teachers responded to a new state test that was designed to encourage them to implement more student-centered instructional practices as embodied in state and national standards (c.f. NCTM, 2000). More specifically, we were interested in gaining a deeper understanding of how teachers feel that the fourth grade test is impacting their instruction, and also in learning more about their actual mathematics teaching. When we began our study, several questions came into focus. They included the following: How did the teachers view the new test? What, if any, changes did they believe that they were making in their actual teaching, and why? As we considered their responses, we became increasingly interested in their actual classroom practices. Some additional questions came into focus. They included the following: Would the teachers build instruction based upon close attention to student thinking? (as cited in, for example, Davis, 1984; Cobb, Wood, Yackel & McNeal, 1993; NCTM, 2000; Klein and Tirosh, 2000; and Schorr, 2000). Would they implement more open-ended types of tasks in their classrooms? Would they encourage students to defend and justify their solutions (as cited, for example in Hanna & Jahnke, 1996; Harel & Sowder, 1998; Maher,

1998; Maher & Martino, 1996)? Would they adopt specific strategies, like using more manipulatives or small group instruction (as cited in Spillane & Zeuli, 1999)? Would they simply ignore the test and not make any changes?

This paper presents two years of data regarding the actual practices of these teachers and their perceptions of how the test has influenced their teaching. Our approach in this research was to observe a sample of 4<sup>th</sup> grade mathematics teachers from across the state, and interview them about their practice and their reactions to the test, including any changes that the test has prompted in their teaching. The test that we focus on is New Jersey's fourth grade Elementary School Performance Assessment (ESPA) that has been in place since 1999. This paper describes the results.

### **Theoretical Framework**

In the last two decades, most states have either introduced or extended their testing of children (Editorial Projects in Education, 2001). As of the 2000-2001 academic year, all 50 states and the District of Columbia have a large-scale testing program in place (Education Week on the Web, 2002). This trend, however, extends beyond the United States (Niss, 1996; Keitel, and Kilpatrick, 1998 as cited in Abrantes, 2001; Firestone and Mayrowetz, 2000; Abrantes, 2001). Some advocates of tests consider these tests to be part of a broader effort to raise educational standards and to make educators accountable for reaching them. They see testing as a way to use the authority of the state to improve teaching and learning and enhance equity by holding all children accountable to the same high standards (O'Day & Smith, 1993). Some maintain that a test that is well designed can prompt teachers to revise their practices because teachers will inevitably "teach to the test", and that can be good if the test is well-designed. Others maintain that content that is emphasized on tests gets emphasized in class, and that untested content either falls out of the curriculum or gets put off until the latter part of the school year (Corbett & Wilson, 1991; McNeil, 2000). The types of items that are placed on the test are also purported to ostensibly influence the types of problems teachers use in class. The argument is that by including items that require students to solve more complex types of problems, teachers will be more likely to provide students with the opportunity to do the same in class. One reason given for the great interest in various forms of performance assessment and portfolios in the 1990s was the hope that tasks requiring students to show their work and explain their answers would promote inquiry-oriented instructional practices (Resnick & Resnick, 1992; Rothman, 1995). Currently many tests combine conventional, multiple-choice formats with other formats intended to measure higher order thinking and problem-solving abilities. However, even when tests employ formats where students construct responses, some of the same risks that are typical of the more traditional tests have been found to occur (Smith, 1996; Stecher & Barron, 1999).

Some opponents of testing believe that extensive testing will encourage measurement of less relevant skills, and reinforce traditional approaches to teaching (McNeil,

2000). There are also those who believe that the effects of state tests have been overstated and that any modest changes in teaching exist alongside what has been conventional practice (Wilson & Floden, 2001). Regardless of the format, the evidence that testing promotes instructional change remains unconvincing or inconclusive at best (Newmann, Bryk, & Nagaoka, 2001; Smith, 1996).

While the research literature on testing remains divided, research in mathematics education (c.f. Schorr and Firestone, 2001, Simon and Tzur, 1999) has consistently shown that changing actual classroom practices is not easily accomplished. Mathematics teaching has a long tradition of focusing on student acquisition of rules and procedures, often with little or no understanding of them. Helping teachers to change their instructional practices toward those recommended in the NCTM Standards requires more than the acquisition of a new strategy or technique. Simon and Tzur (1999) suggest that teachers often have a limited understanding of what the mathematics reforms are about, and mathematics educators and researchers caution that "some of the pedagogical ideas from the NCTM Standards...have been enacted without sufficient attention to students' understanding of mathematics content" (NCTM, 2000, pp. 5-6). Teachers who employ particular methods often insert them into their basic paradigm of teaching without moving towards the more student-centered approach into which they are intended to fit. Thus, specific instructional techniques may not involve students in more compelling and challenging mathematical problem-solving experiences in which they have the opportunity to build and understand different representational systems, defend and justify their solutions, and ultimately develop a deeper understanding of the content.

Based upon the above research in testing, combined with the research on teacher development in mathematics education, our guiding questions were: How do teachers believe that the test is impacting their teaching? and, How are the changes that are being reported manifesting themselves in the actual classrooms?

### **Methods and Procedures**

#### **Sample**

Year 1: The observation study focuses on 63 teachers drawn from two different sources. The first came from a statewide survey of 4<sup>th</sup> grade teachers of mathematics designed to be representative in terms of both district wealth and geographic spread (see Firestone et al., 2001). Ultimately, 22 teachers were selected. The remainder came from a second sample consisting of teachers involved in professional development provided by institutions of higher education.

Year 2: The second year's sample consisted of 28 fourth grade teachers from the first year's professional development districts.

#### **Actual Observations**

Each teacher was observed twice. The classroom researcher kept a running record of the events in the classroom, focusing on the activities of the teacher as well

as capturing the activities of students. The field notes recorded all problem activities and explorations, the materials used, the questions that were posed, the responses that were given—whether by students or teachers, the overall atmosphere of the classroom environment, and any other aspects of the class that they were able to gather.

### **Interviews**

At the conclusion of each lesson, the teachers were asked to respond to a series of open-ended questions about the observed lesson. These included questions relating to the concepts and ideas that the teacher intended to elicit; what changes the teacher might make in future lessons; and how state testing and professional development affected their teaching.

We also asked teachers to describe any professional development or other learning experiences that they might have had and their reactions to the new state test (see Schorr, Firestone and Monfils, 2001; Schorr and Firestone, 2001 for analysis of the first year of study).<sup>2</sup> Briefly, the data suggests that the teachers have adopted new strategies in response to the state test but are not changing their basic approach to teaching mathematics.

### **Coding**

While observations were underway, researchers conducted detailed analyses of records of classroom observations, and adapted several pre-existing coding schemes to be used for coding the classroom data. These were based on the works of Stein, Smith, Henningsen, and Silver (2000); Stigler & Hiebert (1997, 1999); Stein and Smith (1998); and Davis, Wagner, and Shafer, (1997). These codes were selected because they reflected ideas about effective mathematics instruction as indicated in national and state standards. They included attention to the mathematical discourse that emerged, the opportunity for conceptual understanding to take place, the nature of student conjectures, the opportunities students had to share ideas and defend and justify solutions, etc. They were also chosen because we felt that they would supply information on the nature and use of reported strategies (i.e., manipulatives, small group instruction, use of different types of problems and activities, questioning strategies, etc.).

Coding of the classroom observations was performed by six members of the research team who collectively represent a wealth of educational experience including elementary and mathematics classroom teaching, supervision, teacher training, and mathematics education research. Two individuals independently coded each observation—at least one coder was an experienced mathematics education researcher. The other coder also had extensive experience in elementary education.

Interview data were transcribed and entered into a qualitative data analysis software package. Interviews were sorted by question. Responses were analyzed in clusters, as there was considerable overlap in responses given to individual questions.

Within each cluster, responses to specific questions on test preparation practices were reviewed and coded according to emergent themes. For each returning teacher, year 1 and year 2 responses were compared, and trends across teachers were noted. Interviews from 58 of the 63 first year teachers and all 28 of the second year teachers were available for analysis.

### Results

Consistent with our earlier findings (c.f. Schorr and Firestone, 2001; Schorr, Firestone & Monfils, 2001), teachers reported that both the test and their professional development experiences surrounding the state test and implementation of state standards had influenced their teaching. For example, they said that they were using more manipulatives, small group instruction, and open-ended reality based problem activities. Indeed, we found that manipulatives were used in about 60% of all observed lessons. Similarly, students worked in groups for at least a portion of the time, in almost 65% of all observed lessons and in almost half of all cases, teachers made an effort to connect the lessons to the students' real life experiences. Again, consistent with prior results, the adoption of these strategies was not necessarily accompanied by a change in overall approach to teaching mathematics. For example, while manipulatives were used extensively, they were used in a non-algorithmic manner in less than 19% of all observed lessons. This means that the manipulatives were used in ways that did not foster the development of conceptual understanding. In fact, in almost two-thirds of the lessons where manipulatives were used, they were used in a very procedural manner, where the teacher generally told the students exactly what to do with the materials, and the students did it as best they could to mimic what the teacher had done or directed. In many lessons, there was little or no opportunity for the students to develop their own solutions to the problem or to see the relationship between the problem activity and the concrete (or alternative) representations.

The following example will serve as an illustration. In this observation, the teacher supplied the students with pretzels to be used as concrete manipulatives. She then said:

- T: All right, any questions? All right, Mrs. T is going to give you a bag of stick pretzels. What I want you to do is take your [pretzels] and polygon and move it to the side. I'm going to ask you to make many things with your stick pretzels. You can eat them later but you might have to take the stick pretzels and break them in half for some of the activities I want you to do.

In her directions, the teacher specifically told the students, in effect, that although they had been given a concrete material to work with, they would be expected to follow specific procedures. Ms. T. continued as follows:

- T: First thing I want you to do is when I give you the pretzels I want you to form three different pairs of parallel lines. I want parallel lines that

are horizontal, parallel lines that are vertical and parallel lines that are diagonal. That's your first chore. Ok, and you put 'em right on your desk.

Ms. T's demonstration left little to the imagination. Indeed, all they had to do was to take the pretzels and form the shapes that Ms. T. described. In this example, the students had a concrete material (the pretzels), but they were only allowed to do what the teacher wanted them to do. In essence, their role was simply to follow her instructions. Other examples indicate that even when children were given more freedom, the teacher often stopped them without ever asking what they had built, how it connected to the problem or some other representation, or how it compared to what others had built. By telling students exactly how to use the materials, the teacher may have undermined the opportunity for students to better understand the mathematical idea.

A main area that the teachers repeatedly noted as being influenced by the test involved the nature and type of mathematical tasks given to students. They reported that they were now emphasizing more open-ended types of tasks, because of the presence of such items on the test. When we examined the actual mathematical tasks that students were asked to perform, we found that most (77%) involved memorization or doing procedures in an algorithmic manner. Only 3% of all observed lessons involved situations where students were required to do non-algorithmic thinking.

Many teachers also reported that they were interested in having students explain their reasoning. They also said they were interested in having students find and understand multiple strategies for solving problems. Yet despite the fact that many teachers said that they wanted students to explain their own answers, and consider multiple strategies for solving problems, they rarely insisted on such activity. For instance, one code documented whether or not the teacher encouraged students to reflect on the reasonableness of their responses. In almost 80% of all cases the teacher never posed questions that would prompt students to consider whether or not their answers were reasonable. If a student gave an incorrect response, another student was asked to provide a correct answer, but there was little discussion of an appropriate strategy to solve the problem. In the following excerpt, in a discussion involving probability and the fairness of a particular spinner, the teacher asks a potentially good question, but then when the student responds with an observation that could have led to a more mathematically sophisticated discussion, she states the conclusion for the class, thereby eliminating the possibility of extending the knowledge and probing for deeper understanding.

T: Was one of the spinners unfair?

Boy: Yes.

T: Which one was unfair? Rob.

Rob: The second.

T: Why?

Rob: Because one part was bigger than the others.

T: I don't think that we want to play with that spinner. Right?

Class: No.

T: Of course, because many times you will finish in blue. Right?

Of interest in the context of state testing, is the degree to which test preparation directly influences classroom instruction. Our data provide evidence to support claims made by both advocates and critics of state testing. We observed lessons in which teachers openly state that they prepare students for ESPA in the course of their daily instruction. For example, in one such lesson the teacher had the students use pattern blocks to consider the concept of symmetry. To begin, the teacher asked students to classify five plane figures placed on the overhead. After whole class discussion about different methods students had used to group the objects, they moved into a discussion of how some students categorize the objects by the number of lines of symmetry. Students broke into groups and worked on an activity in which they used pattern blocks to "build a mirror image below a dotted line". Then they created similar problems and worked on each other's problems. Students were required to defend their answers by explaining their reasoning. Incorrect responses were tested by students moving objects on the overhead or by paper folding. This lesson, according to the teacher, was one that would prepare students to answer test questions similar to one open ended ESPA item released on the state website in which students are required to use manipulatives to trace the reflection of a plane figure drawn by connecting points plotted in the Cartesian plane, and then discuss the relationship of the area of two figures.

We also observed lessons in which students were drilled on multiple-choice questions taken from district provided ESPA practice books. We found that the students were repeatedly reminded that their answers to open ended practice items would not gain full credit unless they wrote more. In essence, the teachers encouraged the students to write more, as the more they wrote, the more likely they were to get credit. In addition, we heard from teachers, particularly in the low-wealth districts, that selected students were being pulled out of math class for individualized test preparation in order to help them boost their scores. We also heard that again, particularly in low-wealth districts, in the month prior to the test, test review delivered by commercial providers replaced teacher-facilitated math lessons.

We found that many teachers reported that they had participated in professional development designed to improve their practice, their ability to teach in a more "standards-based" manner, and/or their test scores. They also reported that they were under pressure to raise test scores and were subject to surprise district level classroom visits to verify their adoption of strategies such as small group work, and rubric scoring of written responses to open-ended math problems. The teachers reported that many of the demands of this type of district accountability motivating commercial test prepa-

ration and classroom monitoring often impacted their efforts in positive as well as negative ways.

Most teachers referred to the state test as a catalyst for change (“the test is fueling change”) and cited ways in which their practice has changed in response to the test. For example, one teacher stated, “I like the way the questions are challenging and make them think. I think it certainly has affected the way that I’ve taught, I teach, and that I’m very, I’m always looking for opportunities to have an open-ended question somewhere and that’s good.”

The following quote from a teacher in a progressive, high-wealth district summarizes much of what teachers across the state told us about the test and about differential impact across districts:

The benefits of the test are that I think it is making district sit up and take notice that you know what, we can’t teach the way we used to teach because the kids are not getting the skills they need for real life. ...the main thrust of the test is to change the way teachers are teaching in the classroom to match the skills that are needed for the students of today. We can’t teach knowledge. We have to teach skills for getting knowledge. That was what the test was supposed to drive was this kind of teaching in the classroom. ...I do think that the test is reflecting more of the methods we were already using in the classroom. I think that change had taken place before we ever got to the test in many districts. I’m sure there are districts that still aren’t up to that point yet but they are evolving towards that. Especially now the ESPA is in place. They know that their students aren’t prepared. I felt like our students were pretty prepared before we even got the ESPA and saw it for the first time. Much more so. Again, we have made those changes in our curriculum to reflect the ESPA. So, is the test pushing us in a right direction or are we pushing ourselves to match these standardized tests for fourth and eighth grade? That is the big question. It has always been the big question. I will say that I think it is difficult to teach to the test. It probably must be easier to do with other standardized tests like the Iowa and the CAT. Those type of tests lend themselves to teachers teaching to the test. Whereas, this was much more difficult to do that. If you don’t have it in place all year long and in previous years they are not going to be able to do it.

When teachers talked about how test preparation has affected what they are doing in their classrooms, most teachers referred to a more embedded approach to preparing their students for the state test, using phrases like “teaching life skills”, “teaching that reflects the standards”, “critical thinking”, “yearlong preparation”, and stating that by covering the curriculum they were preparing their students for the test. For example, one teacher said, “My classroom is set up to work with ESPA, not separate that I’m gonna stop and train for. My writing folders, right from the beginning my math port-

folios--everything is open-ended questions, rubrics are used from the beginning, language is used. It's just part of our way of life in here."

The interview data also suggest that teachers in the poorest districts are responding differently to the state assessment than teachers in the wealthier districts in terms of change in content and test preparation. For example, when asked about subjects that might have been ignored in the past, one teacher stated that her district did not teach science prior to implementation of the state test. "I think because it wasn't measured on standardized tests. And unfortunately, in an inner-city district, the number one means of deciding what's important in the classroom is what are we gonna be tested on? Reading and math were it, and that's where the focus is."

Many teachers in the disadvantaged districts perceive the test to be a force for improving instruction, while others express doubts about fairness. One teacher in a special needs district expressed praise for the state test, but also talked of the constraints faced by teachers in her district

And in my classroom the ESPA, and the accountability issues of the ESPA for myself and for my students, have made me a better teacher.... I was very pleased with the fact that I was allowed to include both math and technology aspects in my PIP [Professional Improvement Plan] because I was able to indicate that I wanted to improve student growth in math. Not through text study and worksheet completion but through problem-solving activities that was sometimes not finished in a day.

### **Conclusions**

The teachers involved in this research have indicated that they have been motivated to change their styles of teaching as a result of the ESPA test. Indeed, our observations confirm that they do incorporate many of the strategies and techniques that they reported in our interviews (such as small group instruction and the use of manipulatives). This research does not and cannot document just when these strategies first became part of their teaching practice; we can only note that the teachers attribute the implementation of many of them to the test. This study provides evidence that the teaching practices that we noted in our observations, however, are not focused on the more conceptually oriented aspects of instruction. In fact our data, overall, suggests that the teachers we interviewed and observed are adopting new procedures as part of their instructional practice but not changing their basic approach to teaching mathematics. For example, they tend to continue to assign tasks that reinforce a procedural view of mathematics, and classroom discourse does not tend to encourage students to defend and justify solutions. In sum, while many teachers report incorporating standards-based practices in response to the state test, their practice suggests a more surface level adoption of specific strategies rather than a fundamental change toward meaningful mathematics instruction. Those teachers who mentioned professional

development in their interviews claimed that it has influenced their practice and their thoughts about meaningful instruction. Perhaps with appropriate support, teachers who are ready and willing to make changes in their teaching will be able to incorporate practices that will enable children to have access to mathematical instruction that fosters the growth of mathematical thinking.

### Notes

<sup>1</sup>A portion of this paper was presented, in a preliminary format, at the annual meeting of the American Educational Research Association, April 2001 and at PME – NA, October 2001. Neither presentation focused on both the test data and the observation data. This paper was prepared with supports from grants # 9804925 and 9980458 from the National Science Foundation. The opinions stated here are those of the authors and not the National Science Foundation, Rutgers University or Rider University.

<sup>2</sup>Earlier reports (PME-NA, 2001 and AERA, 2001) that relate to this research did not report on the survey data and/or the observational data. In addition, those reports did not focus on the final year of the study as the results had just been coded and were not fully analyzed.

## IS STATE ASSESSMENT A VIABLE TOOL FOR REFLECTION ON CLASSROOM ASSESSMENT?

Tony Thompson  
University of Alabama  
athompso@bamaed.ua.edu

Kolouia Newsome  
East Carolina University  
newsomek@mail.ecu.edu

North Carolina uses *Dimensions of Thinking* (Marzano et al., 1988) as a framework to incorporate higher order thinking in their End-of-Course exams. The goal of this research was to explore whether this effort could also help facilitate the inclusion of higher order thinking in the classroom. Based on reviewing state EOC-related documents and interviews with state officials, a modified teacher-friendly version of the state's assessment framework was created for classroom use. In Spring 2002, over 60 teachers "recreated" the EOC test item development process and analyzed their current classroom assessment practices using the framework. Most teachers found the framework useful; however, a variety of problems including lack of time, lack of "fit," a restricted context, and low state expectations all worked against using the framework effectively in the classroom.

### Introduction

State testing has grown significantly in the US over the past decade. Many critics argue that external, state-mandated testing is detrimental to the quality of instruction and assessment in the classroom by (a) narrowing the curriculum, (b) taking flexibility away from teachers to meet the needs of their students, and (c) forcing teachers to "teach to the test." (Kohn, 2000; McNeil, 2000) However, others propose that if state tests focused more on higher order thinking skills, then these tests might actually help teachers improve classroom instruction and assessment by encouraging teachers to include these thinking skills in the classroom. (Yeh, 2001)

North Carolina (NC) is one of many states with yearly testing, and a goal of promoting higher-order thinking skills. The North Carolina Department of Public Instruction (DPI) officially uses *Principle and Standards for School Mathematics* (NCTM, 2000) and *Dimensions of Thinking* (Marzano et al., 1988) as a theoretical framework to develop test items for their End-of-Course (EOC) exams (DPI, 1999; Munk, 2001). The goal of this research was to explore whether a state's effort to assess higher order thinking skills could help facilitate the inclusion of higher order thinking in the classroom. And in particular, to ascertain if NC's assessment framework was a viable tool for improving higher order thinking in classroom assessment.

### NC's Use of *Dimensions of Thinking*

*Dimensions of Thinking* includes: (1) metacognition; (2) critical and creative thinking; (3) thinking processes; (4) core thinking skills; and (5) the relationship of

content-area knowledge to thinking. Although NC DPI encourages teachers to incorporate all five dimensions in their teaching, only the “core thinking skills” are used as basic organizers in the development of EOC test items. The eight core thinking skills listed in *Dimensions of Thinking (DOT)* include: (1) focusing; (2) information-gathering; (3) remembering; (4) organizing; (5) analyzing; (6) generating; (7) integrating; and (8) evaluating.

The seven thinking skills used by NC DPI to construct EOC test items include knowledge, organizing, applying, analyzing, generating, integrating, and evaluating. In NC DPI’s framework, *focusing*, *information-gathering*, and *remembering* from *DOT* are combined into a single thinking skill called “knowledge.” NC DPI also added the additional thinking skill of *applying* not found in *DOT*. Knowledge and applying appears to originate from Bloom’s Taxonomy which includes knowledge, comprehension, application, analysis, synthesis, and evaluation. Despite combining the thinking skills of *focusing*, *information-gathering*, and *remembering* into the category “knowledge,” *remembering* is the only aspect of this thinking skill used in labeling test items as *knowledge* in NC’s EOC exams. In this case, the actual use of this term is more consistent with Bloom’s Taxonomy than *DOT*.

### Methodology

To frame the professional development experiences for this project, we utilized the ideas of Bryant and Driscoll (1998) to design and facilitate workshops as teachers explored the potential relationship between state and classroom assessment. The “guiding principles for design” included: (a) *purposefulness*: this project was defined around a specific goal / objective with an assessment activity framework specifically created for this project, (b) *connection to the concerns of participants*: this project grew out of our discussions with teachers and their desire to learn more about state testing; (c) *opportunities for exercising judgment*: the project incorporated opportunities for teachers to exercise, share, and discuss their professional judgment through the development and evaluation of state test items; and (d) *opportunities for reflection*: the project was designed to encourage participants to reflect individually and in groups during and after the workshop and relate what they’ve learned to the classroom.

In Fall 2001, the authors met with DPI officials to discuss the process and theoretical framework (*Dimensions of Thinking*) used for constructing mathematics test items for EOC exams. Shortly thereafter, several teachers agreed to recreate the test item development process in a trial workshop. Using feedback from this process and sharing this result with NC DPI officials, the state’s framework was modified to make it more teacher-friendly by grouping the seven thinking skills into three broad categories. In January and February 2002, over 60 teachers participated in two different workshops which involved both analyzing and writing EOC test items. In March 2002, the state assessment framework was modified once again by adding a narrative section to the category descriptors (a more detailed description of the evolution of the assessment framework is provided below).

In creating the workshops the main objectives were to: (a) share the state's process and theoretical framework for creating EOC test items; (b) engage teachers in re-creating the test item development process themselves; and (c) help teachers analyze and compare their current classroom assessment practices with the EOC exams. Following an overview of the process used by DPI to develop test items, each workshop had three small-group activities each followed by whole group discussions.

Activity I: Teachers were given "released" state test items in order to categorize them by thinking skill and level of difficulty. They compared this to the state's categorization for these test items.

Activity II: Teachers wrote their own test items covering a wide range of thinking skills and levels of difficulty. Each group presented their test items for whole group discussion and feedback.

Activity III: Teachers brought copies of their own classroom tests to the workshop. They analyzed their tests by categorizing the questions by thinking skill and level of difficulty and compared this to the proportion of questions found on the EOC exams.

Of these sixty teachers, twenty agreed to continue participating in additional follow-up discussions as they used the assessment framework in their classrooms. For the remainder of the spring semester, they submitted copies of their exams as well as reflections on their experiences in using the assessment framework.

### **Modifying the State's Assessment Framework for Use by Teachers**

Teachers who participate in the development and review of EOC test items describe the process as a rewarding professional development experience. The purpose of this research project was to provide opportunities for teachers to recreate the test item development process to see if it helped them incorporate these higher order thinking skills into the classroom. Our original effort to use the framework "as is" in a "trial workshop" met with little success. Teachers found it too awkward and impractical to use so many different types of thinking skills. In particular, there were large disagreements among teachers when asked to categorize test items by thinking skill. Despite these disagreements, teacher categorizations often fell along similar lines. When reviewing test items, teachers generally grouped "knowledge" items with simple or "one-step" application items. Similarly, "organizing" was often combined with more complex or "multi-step" application items. And finally, "analyzing," "generating," "integrating," and "evaluating" (referred to as the higher order thinking skills) were often used to classify the same test item.

As a result, we modified the state's assessment framework by grouping the seven thinking skills into three broad categories: *Category I*: Knowledge – Applying (simple or "one-step"); *Category II*: Organizing - Applying (more complex or "multi-step");

and *Category III: Analyzing, Generating, Integrating, and Evaluating*. After two further workshops with teachers and discussions with DPI officials, each thinking skill category was provided with a narrative based on how NC DPI used the thinking skills when developing EOC test items and how teachers often interpreted the thinking skills categories. These descriptions are based on the familiarity a student has to a question and whether or not a student is likely to have been taught an algorithm or procedure to solve the problem. The narrative for each of the categories is as follows:

*Category I: Knowledge – Applying (“one-step”).* These are recall questions and simple applications. The problems are very familiar to the student and the student should already know an algorithm or procedure to solve the problem.

*Category II: Organizing - Applying (“multi-step”).* These are more complicated questions and applications, but the student should already know an algorithm or procedure to solve them. The student may also be asked to apply a known procedure to a new situation or the student may need to first organize the information in order to apply a known procedure.

*Category III: Analyzing, Generating, Integrating, & Evaluating (Higher Order Thinking Skills).* How to solve these questions should *not* be immediately apparent. Students will have to think through the problem before choosing a procedure or will have to create their own procedure / method to solve the problem.

The following are examples of released test items and accompanying thinking skills from the NC DPI website.

Category I

- Simplify:  $(6x^3y^3 - 12x^3y^2 + 8x^6y^5) \div 2xy$
- Solve:  $2x + 1 = 5$
- Which of the following is a characteristic of a chord?

Category II

- Express, in terms of  $x$ , the mean of  $(4x^2 - 6)$ ,  $(2x^2 - 3x)$ ,  $(-13x + 3)$
- The US balance of trade is calculated by subtracting imports from exports. If  $0.71x^2 + 2.15x + 67.53$  models exports and  $0.82x^2 + 6.42x + 55.07$  models imports for the period 1970 – 1998 ( $x = 0$  for 1970), find the algebraic expression for the balance of trade.

Category III

- A soup company decides to increase the height of its cans by 30% but to keep the volume the same. Approximately how much must the radius of the can be decreased to keep the volume constant?

- For the line  $y = 3x + 5$ : If the  $y$ -intercept moves to 7 and the slope remains unchanged, how does the  $x$ -intercept change?

In sharing this categorization scheme with DPI officials, they stated that 40% of EOC test items fall in Category I; 20% in Category II, and 20% in Category III. Level of difficulty is another aspect of test item analysis conducted by NC DPI. The level of difficulty of a test item is identified quantitatively through field-testing and qualitatively by teachers. In general, DPI defines easy questions as those 70% of the students would answer correctly; medium questions are those 50% to 60% of the students would answer correctly; and hard test questions are those 20 or 30% of the students would answer correctly. On NC EOC exams, approximately 25% of the items are written at the easy level; 50% at the medium level; and 25% at the hard level.

Thinking skill and level of difficulty are clearly related, but not synonymous. If students rarely have the opportunity to experience Category 3 questions, then all of these questions will be difficult for students to answer. To help teachers differentiate between the thinking skill and the level of difficulty of a test item, an additional framework was created. This framework (in table form) included all possible combinations of thinking skill vs. level of difficulty including the state's percentage goals for each of the nine possible thinking skill–level of difficulty problem types. Teachers used this framework to classify test items from released EOC items or for items they wrote themselves and to place the items into one of the nine categories.

### **Teachers Use of the Framework in the Classroom**

Twenty teachers agreed to use the framework in their classrooms by revising a previous exam and to write a new exam for a future test. Below are examples of Category III questions teachers included on exams that they previously had not. Some teachers took existing questions and extended / modified them to a Category III question. For example,

(Original): "Find the  $x$ -intercepts of the function  $f(x) = x^3 + 3x^2 + 2x$ ."

(Revised): "Explain the connections between the  $x$ -intercepts of the function  $f(x) = x^3 + 3x^2 + 2x$  and the solution to the equation  $x^3 + 3x^2 + 2x = 0$ ."

(Original): "Angela walked along the diagonal of a 30m by 16m rectangular field. How far did she walk?"

(Revised): "Angela took a shortcut by walking along the diagonal of a 30m by 16m rectangular field. How much farther would she have had to walk if she had walked along the edges of the field?"

Another common strategy teachers used to write Category 3 questions involved students explaining their answers. For example:

- "Use the discriminant to predict the number and type of solutions of the equation

tion:  $9x^2 + 6x = -1$ . Use a graphing calculator to check your solution and explain/describe how the graph verifies your answer.”

- “In which of the following triangles can the Pythagorean Theorem be used to find the missing length of a side? Tell why or why not.”
- “Can a right triangle be isosceles? Explain.”
- “Solve  $x^2 + 6x + 2 = 0$ . What solution method did you use? Was this the only choice that seems reasonable? Explain.”
- “Explain how natural logarithms are different from and similar to common logarithms.”
- “Explain why a vertical line has no slope.”

Another strategy used by teachers to create Category III questions was reversing problems. That is, give the students the answer and ask them to generate possible questions. For example:

- “Create a word problem that could be solved using the equation  $x - 6 = 14$ .”
- “Find two different equations with roots of  $-2, 3$ .”

Additional strategies used by teachers to create Category III questions included asking students to

- find an error in a worked problem, then explaining and correcting the error.
- classify equations by type, or comparing/contrasting equations.
- solve problems in more than one way then comparing/contrasting these solution techniques.

### Difficulties in Teachers Using the Framework

Most teachers found our modified version of the state’s assessment framework a useful tool to reflect on tasks and thinking skills used to solve these tasks. In interviews with teachers, most explained that they previously only used two criteria when creating test items: content coverage and degree of difficulty. However, this framework provided them with a new way to analyze/select/generate assessment items. Nonetheless, there were four problem areas that made it difficult for teachers to use the framework in their classroom: lack of time; lack of “fit;” restricted context; and low state expectations.

#### Lack of Time

The first area of difficulty was simply a lack of time. Teachers expressed concern over how long it took to write and grade tests which included higher order thinking skills as well as the amount of time it took to prepare students to be able to answer these types of questions on an exam. In the context of the problems discussed below, many of the teachers expressed concern over whether it was time worth spending.

## Lack of Fit

The state's identification of test items occasionally did not match the *Dimensions of Thinking* framework nor was the state's own classification scheme consistently applied. This made it difficult for teachers to identify questions by thinking skill. Although many of the questions matched thinking skills from *Dimensions of Thinking*, others did not. Our first two examples<sup>1</sup> are mis-categorized by NC DPI as *evaluation* (category 3) questions:

Example 1: Which expression is equal to  $\sqrt{169}$ ?

- a.  $\sqrt{121} + \sqrt{9}$       b.  $\sqrt{196} - \sqrt{1}$       c.  $\sqrt{256} - \sqrt{36}$       d.  $\sqrt{144} + \sqrt{16}$

Example 2: Given  $y = \frac{1}{3}x + 2$  and  $y = 2x - 13$ , which ordered pair below is valid for both equations?

- a.  $(-2, -1)$       b.  $(9, 5)$       c.  $(-\frac{4}{3}, 0)$       d.  $(3, 16)$

In these cases, the term “evaluation” as commonly used in mathematics to “find the value of” is incorrectly used as synonymous with “evaluation” as a thinking skill defined in *Dimensions of Thinking* (evaluation: assessing the reasonableness and quality of ideas).

In *Dimensions of Thinking*, integrating refers to connecting and combining information efficiently into a cohesive statement; changing existing knowledge structures to incorporate new information. Nonetheless, the following question was mis-categorized as a Category 3 “integration” question: The length of a barn is 58 feet and the width is 32 feet. Find the area of the barn. (choices not included here).

Sometimes, test item classification was inconsistently used by NC DPI. On one Algebra I EOC exam in 1998, the question “Which of the following is a rational number?” was classified as a “knowledge” (category 1) question while the exact question was listed as an “organizing” (category 2) question on another Algebra I EOC exam. Similarly, some questions identified as “knowledge” (category 1) on one test were categorized as “analyzing” (category 3) on another despite being the exact same question.

This lack of fit often led teachers to believe they were already teaching for higher order thinking even though “routine” textbook problems continued to dominate their exams ... including those they labeled as Category 3. For example, teachers often categorized question such as “Graph  $y = 2x - 3$ ” and “Find an equation with slope 2 and y-intercept 3” as category 3 (Generating) questions. Although these problems have routine solutions, it was actually consistent with NC DPI's use of the term “generating.” An example EOC test item classified as generating included: The sum of a number and two is five. What is the equation for this statement? Answer among four choices was  $x + 2 = 5$ . However, it is not clearly apparent that this fits with the definition of *generating* in *DOT* where it is described as producing new information, meaning, or ideas; going beyond available information to identify what reasonably

may be true; anticipating next events, or the outcome of a situation; explaining details, examples, or other relevant information.

### Restricted Context

NC EOC tests are limited to multiple choice questions only. This makes it very difficult to use *Dimensions of Thinking* as originally intended. For example, it can be difficult to construct higher order thinking questions that require students to *evaluate* or *generate* using a multiple choice format. As a result, in the workshops, we asked teachers not to limit themselves to multiple choice questions and encouraged them to broaden its use for all types of classroom assessment/activities.

In addition, teachers recognized that due to the restricted context of the exam, many of the questions could be solved using different cognitive skills ... depending on the knowledge and experience of the student. Teachers felt there was no way to tell if a student was required to use a certain thinking skill. Problems initially non-routine when learned in class may become routine on a test. Although a student may have used higher-order thinking skills to learn the mathematics, eventually the problem may become “routine” and higher-order thinking skills no longer needed on the EOC exam. For example, the following question could be reduced to “find the vertex” by many students; yet, it was classified as an “integrating” question by NC DPI:

The height in meters of a ball thrown vertically upward is given by the function  $h = 20t - 4t^2$ . At what time will the ball reach its maximum height and what will be the height at that time?

- |                         |                          |
|-------------------------|--------------------------|
| a. 4 seconds; 25 meters | b. 4 seconds; 16 meters  |
| c. 3 seconds; 45 meters | d. 3 seconds; 40 meters. |

In addition, in the problem above, students are given possible answers. Therefore, students can also substitute the time values to find the corresponding heights. Although this problem does require knowledge of functions, its potential to elicit “higher order” thinking is limited.

### Low Expectations

The vast majority of teachers in our workshops stated that they were unaware of the “thinking skills” framework used to construct EOC items (in particular, none of the teachers had heard of *Dimensions of Thinking*). However, most teachers felt their students were doing fine on the Algebra I EOC exam despite their lack of knowledge of the higher order thinking skills. In discussions with DPI officials regarding the Algebra I EOC exam, students often are not required to answer correctly more than 50% of the questions to pass -- implying a student can miss all “category three” questions and still pass the exam. Thus, the low score needed to pass the exam does not “require” students to learn category 3 questions nor do teachers have to prepare their students to answer these types of questions. (Relatedly, as discussed above, many

category 3 questions were mislabeled as “higher – order” thinking questions further lowering the higher order thinking required on the Algebra I EOC exam). [Of note, deeper investigation into the EOC Geometry exam shows higher expectations and a better fit / consistency with *Dimensions of Thinking*. Not surprising, Geometry EOC scores in NC are lower than Algebra I EOC scores.]

### **Teachers Comments on the Usefulness of the State’s Assessment Framework**

Despite the diverse interpretations and uses of the NC DPI assessment framework, the general consensus among teachers was that they felt it was useful to have a better understanding of how EOC test questions are created and that they felt that they would make at least a few modifications to how they taught and test so their students would be better prepared for the EOC exam. Several teachers commented that after using the state’s assessment framework, they realized they needed to make changes not only to classroom assessment, but instruction as well. As one teacher commented, “When I categorized my test using the framework, I found that 95% of my questions were knowledge [Category I] questions. My new (revised) test is much better because it has a variety of thinking skill levels.” She later continued, “To help my students become successful on this test, I would need to implement more high level thinking as part of my daily instruction so that my students could gain more experience in solving problems of this type.”

Another teacher, after commenting that her students did very poorly on the “revised” test, explained, “But I did gain some valuable insights from this test. I realized that my style of teaching really does sell short my students’ abilities as problem solvers. I try to use discovery type activities, but that is where I seem to stop. Everything after that becomes traditional and rote, especially in my assessments.” In general, although the framework was used and interpreted in diverse manners, teachers stated that the framework was a useful starting point to help them select and create tasks using “thinking skills” as a criterion.

### **Summary**

The goal of this research was to explore whether a state’s effort to assess higher order thinking skills could help facilitate the inclusion of higher order thinking in the classroom. And in particular, to ascertain if NC’s assessment framework was a viable tool for improving higher order thinking in classroom assessment. Our goal was to develop a framework that teachers would find practical in analyzing their classroom assessment practices by helping them introduce “cognitive goals” into their teaching. This project shows that a state’s assessment framework can be a viable tool for reflection on classroom assessment. However, the impact on teachers was diverse, and its long-term impact is unclear. There is little evidence to suggest that the state’s effort to encourage higher order thinking skills on their exams has had much effect in the classroom without additional training on using the state’s assessment framework. Addi-

tional research is needed to continue to follow these teachers to ascertain the impact of their knowledge and use of the state's assessment framework on their teaching and eventually, on the success of their students.

### Note

<sup>1</sup>Some of the examples used in this section are similar (but *not* the same) to those found on the NC Algebra I 1998 EOC exam. The 1998 exam questions are secured by the state and used for EOC practice at the district level.

The objective of the CATCH project<sup>1</sup> is to develop and test a program of professional development to bring about fundamental changes in teachers' instruction by supporting changes in teachers' classroom assessment practices. Classroom observations of middle grades mathematics teachers prior to participation in the CATCH project revealed that most teachers retained conventional assessment practices, even though they were using various reform mathematics curricula. After one year of participation in CATCH, teacher interviews and classroom observations revealed that teachers who initially enacted design principles for classroom assessment sought to apply similar principles to their selection of instructional activities, interpretation of student class work, and their use of instructional assessment. Findings suggest that student-centered instruction is supported by professional development activities that focus on design principles for classroom assessment.

The professional development program we are studying is a product of the Research in Assessment Practices (RAP) project of the National Center for Improving Student Learning and Achievement in Mathematics and Science (NCISLA). From 1996 to 2000, as we studied reform and teachers' approaches to assessing their students in a variety of mathematics and science classrooms, a strategy to develop teachers' formative assessment practices evolved. The CATCH project is studying what is necessary for this strategy to "travel" to new sites. We have found that a key to change is getting teachers to shift their assessment practices toward assessing for understanding. When greater attention is given to developing teachers' expertise with classroom assessment, teachers are better prepared to make principled decisions about the selection of assessment tasks and the interpretation of student work. Then, as teachers broaden their conceptions of classroom assessment and make greater use of instructionally embedded assessment, they are better prepared to make instructional decisions based on the student thinking they listen to and observe. Our belief is that improving the alignment between teachers' instructional decisions and student thinking results in learner-centered instructional environments that are more likely to result in improvements in student achievement (Bransford, Brown, & Cocking, 1999).

### **Theoretical Framework**

There are three theoretical components to our change strategy: (a) a domain view of mathematical content, (b) learning with understanding, and (c) formative assessment.

## Mathematical Domains

Epistemologically organizing mathematical content by domains rather than by a large collection of concepts and skills is not new. Two well-known publications—*On the Shoulders of Giants: New Approaches to Numeracy* (Steen, 1990) and *Mathematics: The Science of Patterns* (Devlin, 1994)—have described mathematics in this manner. To describe each domain, the key features and resources of the domain that are important for students to find, discover, use, or even invent for themselves are identified. The domain view of mathematics differs from conventional perspectives in at least two important ways: First, the emphasis is not on the parts of which things are made but rather on the whole of which things are part (i.e., how concepts and skills in a domain are related) and, in turn, with the relationship of those parts to other parts, other domains, and ideas in other disciplines. Second, the domain view rests on the meaning of signs, symbols, terms, and other mathematical representations—the language that humans have invented to communicate with each other about the ideas in the domain. In fact, students should experience the need for the elements of the language of mathematics, and as a consequence, teachers must introduce and negotiate with the students the meanings and use of those elements.

## Learning with Understanding

In any mathematical domain, learning with understanding occurs on a widespread basis in classrooms that provide students with opportunities to (a) develop appropriate mathematical relationships, (b) extend and apply their mathematical knowledge, (c) reflect on their own mathematical experiences, (d) articulate what they know, and (e) make mathematical knowledge their own (Carpenter & Lehrer, 1999). To accomplish this, the ideas in any domain need to be structured according to *hypothetical learning trajectories* (Simon, 1995) to help teachers plan and carry out instruction so that students progress from informal, to preformal, and then to formal understanding of the domain.

## Formative Assessment

From an assessment perspective, a hypothetical learning trajectory can be viewed as a loosely sequenced subset of benchmark evidence for student learning with understanding in a particular domain. The quantity and quality of evidence of student learning are bounded by the practical means by which teachers can reasonably assess individual and collective learning within a classroom setting through formal, informal, and instructional assessment methods. In this sense, *hypothetical assessment trajectories* are organizational frameworks to locate student thinking on a network of developmental paths that are accessible and achievable through appropriate sequencing of learning opportunities.

Although research confirms the contention that formative assessment supports student learning (Black & William, 1998) and can be used to facilitate learning with

understanding (Shepard, 2000), many mathematics teachers show limited understanding of the ways formative assessment can be fully incorporated into their classroom practices (Fennema & Nelson, 1997; Fennema & Romberg, 1999). As a result, teachers often find it difficult to make didactic decisions based on their students' work and therefore leave their students with incomplete information about their progress (Romberg, 1999). Students in such classrooms can find themselves at a loss in assessing what they know, or don't know, reinforcing flawed procedures and mathematical misconceptions. To teach for understanding, teachers must first assess students' prior knowledge, skills, and understanding, and then use this information as a point of departure for instruction. As students progress, teachers must continue to monitor their progress, not in terms of correct or incorrect answers on some percentage scale, but in the broader and deeper sense of their conceptions of mathematical content and their growing ability to adapt what they understand to solve unfamiliar problems embedded in new contexts.

To operationalize assessment trajectories, teachers need to value students' informal knowledge as instructional anchors. As argued by Kilpatrick, Swafford, and Findell (Kilpatrick, Swafford, & Findell, 2001) in *Adding It Up*, "learning with understanding involves connecting and organizing knowledge, learning builds on what children already know, and formal school instruction should take advantage of children's informal everyday knowledge of mathematics" (p. 342). Whereas conventional classroom assessment focuses primarily on student outcomes and student recall of formal knowledge and procedures, assessing for student understanding requires that teachers attend to students' incoming knowledge and the progression in student knowledge across a wider range of informal, preformal, and formal representations. Even experienced teachers with degrees in mathematics struggle with how to make use of students' informal knowledge and emergent student strategies. Teachers who value students' informal knowledge assess and expand on their thinking in ways that transcend the objectives of a particular activity, thereby bridging content across lessons and providing opportunities for students to apply knowledge in new ways.

Building from the results of a series of in-depth studies with middle grades mathematics teachers that demonstrated the value of developing teacher expertise with classroom assessment (Romberg, in press), our goal in the CATCH project was to study the design, implementation, and impact on teacher practice of a professional development program to support teacher assessment of student understanding. Over the duration of the study we will also analyze how changes in teachers' assessment practices impact student achievement results on compulsory state and district assessments. The focus of this report is to report a subset of findings from this study in response to the following question: How do teachers' assessment practices change as a result of their participation in this professional development program?

### Approach and Methods

To have an impact on teacher practice, professional development activities must leverage mutually supportive principles that promote teacher learning. King and Newmann (2001) concluded that teacher learning is most likely to occur when:

- teachers can concentrate on instruction and student outcomes in the specific contexts in which they teach;
- teachers have sustained opportunities to study, to experiment with, and to receive helpful feedback on specific innovations;
- teachers have opportunities to collaborate with professional peers, both within and outside of their schools, along with access to the expertise of external researchers and program developers; and
- teachers have influence over the substance and process of professional development (p. 86).

Each of the principles described above is consistent with the design of professional development activities for our work with teachers in CATCH.

Our aim was to train professional development cadres at each of the participating sites who would then conduct professional development programs on classroom assessment for teachers in their respective districts. The objectives of the institute were to articulate the goals of the project, present examples and activities to communicate classroom assessment principles (e.g., making one's assessment goals explicit, considering features of assessment task design, scoring and grading student work), and provide opportunities for cross-district collaboration and team building. Participants were involved in adapting and constructing formative assessment instruments, which they later used in classroom experiments. Materials developed at the institute were consistent with the principles of mathematical literacy described in OECD's (1999) *Measuring Student Knowledge and Skills: A New Framework for Assessment*. Participants were also provided with a number of existing assessment resources they could adapt for their own use — e.g., *The Great Assessment Picture Book* (Dekker & Querrele, 2002) and *AssessMath!* (Cappo, de Lange, & Romberg, 1999). Attention was also given to critique of existing assessments and how to select instruments to meet their own goals. In general, the seminar emphasized more constructive ways to assess student understanding and gave teachers the opportunity to discuss how such ideas could be incorporated into their classroom practice and supported through ongoing professional development. The initial CATCH seminar served as an example for the summer seminars that were conducted by lead teachers.

Our support efforts have since shifted to providing technical support to teachers as they design assessment tasks, participating in monthly meetings (when possible), and supporting teachers and administrators in the design of local professional development for new cohorts of teachers. Local professional development activities facilitated by

the research team and lead teachers were designed to promote the following developmental model:

- During the initial CATCH summer institute, lead teachers and administrators critique and develop greater understanding of existing assessment instruments;
- Teachers select and adapt assessment instruments for their own use with students and report about results during monthly and ad hoc meetings with colleagues;
- In considering and using these instruments, teachers examine the role and function of assessment instruments versus the desired learning outcomes and the potential for positive feedback;
- Scoring and grading of student work is used to provide insight into student (mis)conceptions that guide instruction;
- Teachers implement design principles for classroom assessment and learn how a series of items can be constructed to design balanced assessments that reflect a hypothetical assessment trajectory. This provides students with the opportunity to demonstrate the full range of mathematical competencies including making mathematical arguments, non-routine problem solving, developing their own models and inventing new strategies;
- Teachers explore assessment opportunities embedded within instructional contexts, learn how to balance the use of formal and instructional assessment, and examine the relationship between classroom assessment and student achievement on external assessments;
- Teachers inform their colleagues during successive summer institutes, thus helping ideas and outcomes of the CATCH project to “travel” to new classrooms, schools and districts.

### **Participants and Data Collection**

The participants in this study include professional development cadres (lead teachers, staff developers and district administrators) from two school districts. District A is a small urban/suburban district serving over 3,000 students in which lead teachers work with a student population that is predominantly European American (85%), with approximately 30% receiving free or reduced-cost meals. District B is a large urban district in Eastern United States in which lead teachers work in middle schools with a school population of predominantly African American and Hispanic students, with more than 75% receiving free or reduced-cost meals. In March 2001, fifteen teachers and administrators from Districts A and B participated in the initial CATCH institute. After one year, just over 100 teachers across both districts had participated in CATCH professional development activities.

Data collection during the first year of the study focused on the emerging classroom assessment practices of lead teachers. These practices were documented through

an initial survey, classroom observation protocols, and teacher interviews. Two interviews were administered every semester and classroom observations were completed every eight weeks. Changes in teachers' assessment practices were also documented via an assessment portfolio, which included all formal assessments administered by each teacher, and samples of student work.

### Results

Overall, teachers became more aware of what they were doing (and not doing) to assess student understanding. In monthly meetings and summer institutes held during the 1<sup>st</sup> year of the CATCH project, both district teams chose to emphasize the selection and design of tasks according to a tri-level Dutch assessment pyramid (see Dekker & Querelle, 2002). As lead teachers articulated classroom assessment principles as presenters during their respective summer institutes they revealed the assessment aspects from the initial CATCH institute they found relevant and demonstrated their degree of ownership of assessment theory and practice. Teacher interviews and classroom observations revealed emergent assessment practices and increased attention to assessment opportunities that occurred during instruction. Classroom observations and teachers' assessment portfolios from both research sites indicated greater teacher use of tasks that provided students opportunities to demonstrate a range of mathematical understanding. For this research report interviews will be used to highlight teachers' justification for using more cognitively demanding tasks.

#### Selection and Design of Tasks to Assess Student Understanding

Teachers at both research sites chose to apply the Dutch assessment pyramid in their own classrooms and shared these design principles with colleagues in local CATCH institutes. Lead teachers realized that most assessment instruments used at their schools consisted of items that assessed only basic skills, facts, and routine procedures (*Level I questions*), often in short-answer or multiple-choice format. Teachers found that they rarely used problems designed to deepen student knowledge and understanding as students use basic skills and routine procedures in unfamiliar problem contexts and choose appropriate mathematical tools to solve problems (*Level II questions*). Nonexistent in teachers' classroom assessments was the use of questions to encourage generalization, mathematical reasoning, and argumentation\* (*Level III questions*). Teachers concluded that they were not giving students opportunities to gain ownership of the mathematical content and were only asking students to reproduce what they had been practicing. In a process described as "leveling," teachers analyzed their own assessments to discern the reasoning elicited by different assessment tasks. As one teacher noted, the most helpful aspect of CATCH was "looking at questions on levels and leveling and really having the opportunity to re-examine myself through that information that I have gotten [from students]."

The Dutch assessment pyramid was often used by teachers to justify greater use of projects, extension problems and prompts requiring written explanations.

- One of the things that I am doing is [with] a group of four girls who really are together and getting it. I try to get over to them ... and push them over the edge a little bit more with trying to get them to think a little, because they can. (Ms. Pitkin, District B, 01/28/02)
- I like to put a question on each exam that allows them to think about and maybe apply some other information they already know to what they, to what we are doing. ... They really have been doing well with them and really understood why they get these [problems]. Explaining why this formula is so and not just saying this is how it is [written in] the math guide. (Ms. Graves, District B, 01/31/02)

In District B, the Dutch assessment pyramid was presented at the local CATCH institute as a model for classroom assessment that was consistent with compulsory district and state assessments, which included problems requiring students to provide mathematical explanations and engage in non-routine problem solving.

- I think it differs from last year because I am looking more to see if kids are writing more. Last year they didn't do a lot of writing. This year I am trying to focus on the things that are outlined in their testing, for standardized tests. A lot of the things that they have to do require that the children explain their answers in detail. Not always with numbers, but with words. So it is a little bit different. I am not looking for just computation this year. It is computation plus an explanation. (Ms. St. Pierre, District B, 01/30/02).

### **Reduced Emphasis on Formal Assessment**

As teachers gave greater attention to assessment design they began to view assessment opportunities in other aspects of classroom practice. The attention to task design allowed teachers to apply the same principles to tasks used in particular phases of the teaching-learning cycle. Tasks used for instructional activities, class work and homework were now potential assessment opportunities. As a result, several teachers reduced their reliance on tests and quizzes as assessment instruments.

- I think I am getting away from [using] as many tests, as many quizzes. It seems to be more the observation and discussion. Show me an example of how your work is done in class or something like that. I don't feel the need to test as much. It seems like a waste of time. I know what they are going to do pretty much [and] it seems to be just a waste of time now, the process of formal testing. So I try to cut that back. We were in the past giving two tests per chapter and have cut it back to one. (Mr. Lemke, District A, 03/05/02)
- I think the subtler the assessment probably the better it is.... I walk around all the time. I can get more out of that assessment of just looking and seeing what the

kids are doing. And for one thing it is a lot faster than having to put it on a piece of paper. And it is immediate and it is very quick and it doesn't have to necessarily break the flow of the class. (Ms. Edwards, District A, 02/15/02)

- I do more observation of classwork and homework as a tool than I do my test. And that is the truth! (Ms. Carter, District B, 01/31/02)
- Observation in the classroom. Just watching them as they work. Listening. So keeping a better record, a more accurate record of who is answering what. Before it was kind of like a general sense of things. And now I kind of have a more detailed recording of who answers, how often they answer correctly, who doesn't answer, who will answer if I call on them and things like that. So that is a little different from last year. (Ms. Kruger, District B, 01/28/02)

However, as teachers gave greater attention to observational assessment some struggled with how to document such information. Teachers were not interested in using evidence gathered through observational assessment for reporting or grading. Rather, teachers viewed record-keeping as a way to bring greater clarity to the "hodge-podge of information in their head"—a tool to support further reflection on student thinking.

Several teachers described changes to their practice of scoring and grading student work. With regard to student performance, they grew to value qualitative over quantitative information. Student models and explanations were of greater interest than aggregate scores. In order to devote more time to interpreting student work, teachers were more selective in the student work they collected and scored. Becky, a teacher with over 30 years experience teaching middle grades students explained,

- I assess formally less often. ... and I tell the kids I expect them to monitor their progress to get their needs met. Major shift. Major shift. I talk to teachers in my building who have hundreds of grades per quarter. 'Hey, guys! We've got to get past this!' ... You don't have to do that. You have to give the kids feedback.... You have to discuss it. Answer their questions. But you don't have to grade it. You don't even have to collect it. And it seems like any person with two ounces of brains could figure out that they can't possibly grade 120 papers every night and stay sane. But somebody had to tell me that! (Ms. Chamberlain, District A, 02/15/02)

### **Impact on Classroom Instruction**

In addition to demonstrating greater use of Level II and III problems in their formal assessments, teachers began to interpret instructional activities and problems in terms of the level of reasoning required. Several participating teachers used principles of assessment design to evaluate instructional activities and motivate questioning techniques to extend student reasoning. This entrée to instructionally embedded assessment began to emerge in the second round of post-observation interviews, in

which teachers began describing instructional activities, class work and homework problems in terms of Levels I, II, and III reasoning. As explained by one teacher,

- Not just in the design of the test, but in the actual problem work that they are doing, students need to be able to take their concept or their knowledge of the concept and reapply it in a slightly different way. Maybe related, but different. (Ms. Petersen, District A, 03/05/02)

Ms. Graves, a District B lead teacher, observed that the curriculum she used did not appear to include enough Level II and III problems. Therefore, she began to supplement student class work with problems requiring further application and generalization of concepts and adapted her curriculum to extend student thinking.

As teachers gained confidence in the design of assessment tasks, they began to apply the same design principles to the questions they used during instruction. During the first round of observations, the trajectory of the lesson followed the outline of the curriculum and teachers restricted their exploration of student thinking to questions as written in the textbook. By the third round of classroom observations, several teachers in District A demonstrated greater use of questions to probe and encourage elaboration of student responses which emerged during the activity. Teachers were more responsive to student thinking and used “their own questions” to facilitate classroom discourse.

The emergence of student-centered pedagogy was observed in Mr. Lemke’s class. In a post-observation interview, Mr. Lemke identified the questions he developed “on-the-fly” as giving greater insight into student thinking and attributed his improved instructional decisions and use of questions to a shift in the locus of instructional assessment, from “as a class” to “to the kid.”

- I guess I am moving toward a better assessment. I still think I have a long way to go. I guess I should be able to predict better what is coming for kids and I think I am getting better at making decisions as I go along. I think I can read the kids better than I could two years ago. ‘To the kid’ instead of ‘as a class.’ [Assessment] ‘as a class’ was not as helpful. I think now I can pretty much ‘to the kid’ know what they are doing. (Mr. Lemke, District A, 03/05/02).

### **Conclusion**

Teachers who teach for understanding find the need to design tasks to assess Level II and III goals in order to assess for understanding. As teachers operationalize this assessment design model, they begin to rethink the learning objectives of their curricula and the questions they use during instructional activities. To make sense of students’ mathematical representations elicited by Level II and III questions, teachers need to have the opportunity to construct explanatory models that relate students’ verbal and written artifacts to hypothetical assessment trajectories and models of progressive formalization.

Our experience shows that teachers, and subsequently their students, benefit greatly from exploring features of classroom assessment, such as the design of assessment tasks, the interpretation of students' written and verbal responses, and strategies for eliciting or responding to student ideas during instruction. But teachers have to feel the need for change themselves: they must recognize the limited information their current assessment practices provide, they must realize the necessity of using tasks and practices that can reveal student understanding and they must view teaching for understanding as an important goal. By integrating assessment and instruction, teachers will develop an informed basis for making instructional decisions. These developments lead to greater student understanding of mathematics and improve student achievement.

## **DEVELOPING A MULTI-TIER ASSESSMENT DESIGN IN MATHEMATICS EDUCATION: THE EFIT AND EMAT PROJECT**

Guadalupe Carmona  
Purdue University  
lupitacarmona@purdue.edu

Teresa Rojano Ceballos  
Cinvestav-IPN  
trojano@mail.cinvestav.mx

When coordinating a complex and rapidly expanding project in Mathematics Education that involves developmental, research, and implementation components all intrinsically changing, how does one go in evaluating and assessing? We were obliged to answer this question when the implementation of the EFIT-EMAT (Teaching Physics and Mathematics with Technology) Projects were supported by the Ministry of Education in Mexico. In this presentation we will justify the use of a multi-tier assessment design by giving examples of how this design encourages interaction and helps document and give opportunistic feedback to all the participants, and thus, leads to the development of the EFIT-EMAT Project. We will also describe thought-revealing activities for students and teachers, and how these tools have been used to document and evaluate students' mathematical understanding and teachers' mathematical practice.

### **Context: The EFIT and EMAT Projects**

The EFIT (Enseñanza de la Física con Tecnología, or Teaching Physics with Technology) and EMAT (Enseñanza de las Matemáticas con Tecnología, or Teaching Mathematics with Technology) Projects for public middle schools were supported by the Ministry of Education in Mexico as a response to the Educational Reform (SEP, 1994). This reform's goals are to (a) increase quality in the teaching and learning of Science and Mathematics (including teachers, students, curriculum, theoretical perspective), (b) increase coverage of education, and (c) enhance professional development of teachers in Science and Mathematics. Thus, the EFIT and EMAT Projects were supported at a pilot stage from 1997 to 2000 in 32 schools countrywide to assess feasibility for further expansion. Characteristics of these projects included the implementation of a pedagogical model, aligned to the new curriculum, and using pieces of technology to create a classroom environment that would allow a learning approach that wouldn't be possible to achieve without these components.

The pedagogical model integrates innovative elements, like a transformation of the role of the traditional teacher to a more active guide and facilitator; the encouragement of collaborative learning to discuss and solve scientific and mathematical projects; the awareness of a closer and more meaningful relationship between students' every day life events and math and science in the classroom; the use of the technology as a mediated tool; and the development of activities that incorporate the technology, the pedagogical approach, and the reformed curriculum.

Classrooms are equipped 10-15 student computers; a teacher computer, local access network connections with the Internet; a printer; and distance communication via Red Escolar (Educational Network). For the EFIT Project, software included Interactive Physics, Micro-computer based lab (sensors), and LXR Test. For the EMAT Project, software included Cabri-Géomètre, Spread Sheet, Stella, SimCalc Mathworlds, and Calculator TI-92.

After three years, the Ministry of Education assessed the results (Rojano, Moreno, Bonilla, & Perrusquía, 1999) and decided to support an expansion of this project to other states and schools, including Telesecundarias (middle schools offered through satellite system devices, mainly aiming at rural areas) and Normales (Normal Schools). This expansion, occurring in the next 5 years (SEP, 2001), urges us to re-think the evaluation and assessment strategies used in the pilot stages, and to formulate a feasible plan for such an up-scaled venture. A plan that in addition to evaluation and assessment, will also promote implementation, developmental, and research components.

The main goals to consider for the evaluation and assessment of the EFIT and EMAT projects are: 1) To document the development, including conditions that enhance or hinder growth, 2) To help in the decision-making instances of different participants, and 3) To give access of documentation to all the Project participants as feedback.

### **Research Design: Multi-tier Design Experiment**

The need for an evaluation and assessment plan that is dynamic, iterative, adaptive, and adoptive, leads us to consider design experiments (Brown, 1992) as an appropriate framework. Lesh and Kelly (2000) describe a multi-tier design experiment (MTDE) as a complex system that allows researchers to document and analyze the development in which students, teachers, schools, parents, and researchers interact. MTDE's involve at least three levels of investigators: students, teachers, and researchers, all of whom interact and interweave through their experiences and roles to develop towards common goals. For example, Tier 1 may focus on the nature of students' developing knowledge and abilities; Tier 2 may be aimed at investigating teachers' developing assumptions about the nature of students' mathematical knowledge and abilities; and Tier 3 may center on the researchers' conceptions about the nature of students' and teachers' developing knowledge and abilities. Each tier can be thought of as a longitudinal development study – all of the tiers interact and affect the others. Thus, a MTDE provides a complex methodology to collect and analyze documentation on student/teacher development, and their mathematical ideas.

### **Methodologies for Documentation**

Aspects we anticipate should be documented include: 1. Educational community profile, 2. Technology, 3. Curriculum content, 4. Motivation, and 5. Pedagogy. For the design, we'll consider these methodologies:

- (a) **Standardized Testing:** Including diagnostic computer and paper-based student testing and pre-testing to evaluate initial conceptions on mathematics and scientific content. Testing at the end of the school year will allow us to do a pre and post-test analysis. The methodologies used to design, collect, and analyze these tests involve item response theory and other statistical methods. Software that will help us achieve these goals is LXR Test.
- (b) **Qualitative Tools:** Aimed for teachers, instructors, parents, school principals, and administrators, these include the use of questionnaires, interviews, observation guides, and journals. The methodologies used to design, collect, and analyze these tools are qualitative, and involve different approaches (Miles & Huberman, 1994).
- (c) **Thought-revealing Activities (TRA):** Designed to engage students in developing math and scientific concepts, these can also be used to document participant development within the project. They reveal the way students think about a given real-life situation which is modeled through mathematics (Lesh, Hoover, Hole, Kelly, & Post, 2000). The problem is solved by groups of 3-5 students who create a mathematical model. An identified client requires the students' solution in order to solve the problem. To implement the model adequately, the students must clearly describe their thinking processes and justify the solution. In this way, students are forced into a cognitive situation where they can refine their ideas iteratively until they develop a construct that is useful and meaningful for them and the client. Ultimately, they need to describe, explain, manipulate, or predict the behavior of the real world system to support their solution as the best option. As in real life, there is not a single solution, but there are optimal ways to solve the problem. Because of their characteristics, TRA's blur the distinction between instruction and assessment. They can be used for student assessment because (i) students' learning is being assessed WHILE students are learning, and (ii) since these problem-solving situations promote learning, they are not taking time away from learning to assess their thinking. TRA's allow students to document their own thinking and learning development locally (in a single solving episode) and longitudinally (solving a collection of activities during the school year). Thus, they allow teachers and researchers to access a trail of documentation for ways of thinking. When used in a classroom context, teachers find themselves in a situation where their role is shifted to become facilitators, observers, mentors, and learners – all at the same time. In addition, the teacher must also adjust to collaborative learning in the classroom. Therefore, when teachers begin using TRA's for students, they gradually shift towards new ways of teaching that are more consistent with the EFIT-EMAT Project. Analogously, TRA's can be designed for teachers, providing trails of documentation of their development within the multi-tier design experiment (Carmona, 2000).

In the presentation, an example of one TRA for students and one for teachers will be shown, and how these can document students' and teachers' development (locally and longitudinally) and how these activities give opportunistic feedback for teachers, parents, administrators, and researchers.

### Note

Special acknowledgements to the Ministry of Education in Mexico, CONACyT for funding the research project: Incorporación de nuevas tecnologías a la cultura escolar (Grant no. G26338S), Purdue Research Foundation (Grant no. 690/1442-3527), and Dr. Richard Lesh for his contributions and advice on the EFIT-EMAT Project.

## TIMSS 1999 DATA: ONE SINGAPOREAN'S PERSPECTIVE

Kien Lim

San Diego State University

kienlim@mail.sdsu.edu

Singapore ranked first among 38 participating countries in the 1999 Mathematics Test in the Third International Mathematics and Science Study (TIMSS). Their achievement will be considered from two perspectives: (1) the correspondence between the TIMSS Mathematics Test and Singapore's high-stakes mathematics exam for sixth graders, and (2) a personal reflection on the roles of schooling and testing in Singapore's society.

Singapore's Secondary 2 (equivalent to U.S. eighth grade) students performed significantly better than U.S. eighth graders in each of the five content areas covered by the 1999 Mathematics Test. Using the data and categories in TIMSS 1999, this paper identifies the test items on which the Singapore students outperformed the U.S. students. These items were compared with test preparation materials used widely by Singapore students for the national examination, *Primary School Leaving Examination* (PSLE).

These analyses were based on two data sources: (1) the 82 questions in *TIMSS 1999 Mathematics: Released Set for Eighth Grade* and (2) the weighted summary statistics for each participating country on each mathematics item as listed in *Main Survey TIMSS Report* (available: [http://www.timss.com/timss1999i/timss\\_test.html](http://www.timss.com/timss1999i/timss_test.html)). U.S. students performed better than Singapore students in only three out of the 82 released items. All three were multiple-choice items, two in *probability* and one in *number sense*, two in *knowing* and one in *investigating and solving problems*.

Among the five content areas, Singapore students performed significantly better than U.S. students in *fractions and number sense* and *measurement*; among the performance expectation categories, they performed better in *investigating and solving problems*, and *communicating and reasoning*. Many of the *investigating and solving problems* items are considered routine procedures for Singapore students as similar practice problems in PSLE preparation materials can be easily found to match 17 of these 25 items. Other than probability, the items in the released sets are well within the national syllabus for the *Primary Mathematics Programme* (available: [http://www1.moe.edu.sg/syllabuses/doc/Maths\\_Pri.pdf](http://www1.moe.edu.sg/syllabuses/doc/Maths_Pri.pdf)). Singapore students will generally find the TIMSS Mathematics Test easy because they took the PSLE Mathematics two years prior.

## Singapore's Educational Climate

The mathematics curriculum in Singapore is examination driven. Primary education is dedicated to preparing students for the PSLE, in which results are used to assign Singapore students to either the *Special*, *Express* or *Normal streams* for their

secondary education. Secondary 2 exam results are used to track them into either the science, technical or arts streams. Students must pass the General Certificate of Education (GCE) "O" Level examination to pursue "pre-university" education; each student's grades will determine his or her admission into either junior colleges (two-year program) or pre-university centers (three-year).

The educational environment in Singapore is highly competitive. Not only do students compete among themselves, schools compete to attract good students. Students must perform well in the PSLE to gain admission into higher-ranking secondary schools, in the GCE "O" Level exam to get into top junior colleges, and in the GCE "A" Level exam to be admitted into their national universities. The pressure to perform well on exams may help explain why Singapore students reported spending more out-of-school time doing homework in mathematics than U.S. students (Mullis et al., 2000).

Having experienced the education system in both Singapore and the U.S., I am aware of many social and cultural differences affecting mathematics education. For example, citizens in Singapore generally place greater importance on education and emphasis on effort. Singapore students are generally more competitive and motivated to excel academically, and they face more social pressure of having to meet their parents' and teachers' expectations.

To benefit from comparative studies, differences in cultural traditions must be considered (Graf & Leung, 2000). Based on my reflections on my experience in both countries, I wish to share my perspectives on (1) how culture affects education, (2) how the Singapore education system is designed to meet the needs of the country rather than those of the individuals, and (3) why care must be taken when we import educational ideas (e.g., Singapore textbooks) from another country. There is more to the story than can be told solely by test scores.

## MIDDLE SCHOOL MATHEMATICS TEACHERS' UNDERSTANDING OF CLASSROOM ASSESSMENT

Jean Hallagan Palm  
Syracuse University  
jhpalm@syr.edu

Despite the reformed vision of assessment in mathematics classrooms, vast differences exist in how teachers use and view classroom assessment (Stiggins, 1999). A pervasive focus on summative assessment and the use of lower level recall permeates classrooms (Black & Wiliam, 1998). This perspective raises important questions about mathematics teachers' understanding of classroom assessment. The purpose of this study was to examine a cadre of middle school mathematics teachers' understanding of their assessment practices as they began to implement the reform-based middle school curriculum *Connected Mathematics* (Lappan, Fey, Fitzgerald, Friel, & Phillips, 1998). Classroom assessment of student work is construed in a broad manner and is intended to include all traditional methods such as quizzes and tests as well as homework, class assignments, observation, group work and questioning techniques. Related research questions included: How do the teachers use classroom assessment? What types of assessments do they use? How does the curriculum influence their assessment practice? How do teachers negotiate classroom assessment within the broader context of mandatory state assessments in eighth grade?

Six female teachers in two middle schools in an urban area in the northeastern United States were recruited from schools implementing the reform-based middle school mathematics curriculum *Connected Mathematics*. Teachers in both buildings met regularly and at least weekly to discuss the curriculum. Teaching experience ranged from 6 to 28 years. The intent was not to follow individuals per se; rather, the intent was to see how the group as a whole understood their classroom assessment practice. The goal was to describe how teachers understand their classroom assessment practices through semi-structured interviews, observation and assessment artifact collection. The data collected in this study consisted of three semi-structured interviews, conducted at the beginning of the school year, at the end of the first marking period in early November, and at the end of the second marking period at the end of January; classroom observations; and collection of assessment artifacts when they deviated from the curriculum.

The results of this study indicate a multifaceted picture of the teachers' understanding of classroom assessment. How these teachers understand classroom assessment is inextricably linked to the looming state exams given at the end of eighth grade. However, the teachers understood classroom assessment to be much broader than "teaching to the test" and engaged in reformed practices. Analysis showed how the teachers knew what students had learned. The results show great promise that these teachers,

involved in ongoing professional development, and utilizing a reformed middle school mathematics curriculum understand assessment to be far beyond formal quizzes and tests. These teachers' perception of assessment includes a formative component that is broader than traditionally summative and formal modes.

## SPATIAL VISUALIZATION: DO TESTS ASSESS WHAT WE THINK THEY ASSESS?

Kathryn Pope  
Charity Middle School

Ann R. Crawford  
UNC - Wilmington

Results from the sixth National Mathematics Assessment recommended more experience with concrete models to visualize and explore concepts (Strutchens & Blume, 1997). Studies have enumerated the strategies and errors that middle grade students utilize in counting the total cubes in a 3-D arrangement of cubes (Battista & Clements, 1996; Battista, 1999). The purpose of this study was to determine if spatial visualization instruction at Van Hiele level 0 would improve learning in volume and surface area (Van Hiele level 1 and 2) with eighth graders. To extend past research, visualization errors were analyzed for a surface area open-ended problem.

The teaching experiment was conducted in regular eighth grade class settings over two weeks in a rural middle school. With the experimental group ( $n = 14$ ), the teacher introduced volume and surface area with visualization activities using linking cubes then moved to the formulas for the calculations. The comparison group ( $n = 15$ ) studied volume and surface area from traditional pictures on the board and in the textbook. Each group was given a pretest in which students calculated volume for two prisms, two cylinders, one pyramid, and one cone and surface area for two prisms and two cylinders. For the posttest, ten problems similar to the pretest were given on a 20 item unit test. In addition, the posttest included a surface area problem in which students counted the surface area visualized in squares rather than using a formula. Standardized state criterion referenced tests given at the end of the 7<sup>th</sup> and 8<sup>th</sup> grade were reported.

**Table 1.** Experimental and Comparison Means

|                              | 7 <sup>th</sup> Grade<br>State Test | 8 <sup>th</sup> Grade<br>State Test | Pretest<br>% Correct | Posttest<br>% Correct |
|------------------------------|-------------------------------------|-------------------------------------|----------------------|-----------------------|
| Experimental<br>( $n = 14$ ) | 167.8                               | 174.4                               | 5.7                  | 60.9                  |
| Comparison<br>( $n = 15$ )   | 168.3                               | 173.9                               | 3.6                  | 61.2                  |

Quantitative results did not show improvement in volume and surface area learning by using linking cubes for visualization. However, in an interview, the teacher explained, "Yes, the manipulatives did help!" She noted, "In class, comparison students experienced difficulty in comprehending the figures and determining measurements for the formulas. She added, "The experimental group was able to transfer the measurements from the figures to the formulas".

With the visualization surface area problem, only 4 students in the comparison group attempted the problem while 9 students in the experimental group attempted it. Only one student from each group gave the correct answer and explanation. However, the 9 students in the experimental group gave explanations using the concept of surface area. Many student errors were in miscounting the surfaces.

All students scored at Level III (170) on the state test, "mastery of grade-level subject matter and skills and well prepared for the next grade level". These results reveal a discrepancy between student understanding shown in the open-ended question and posttest scores and also the achievement measured by the state test.

## THE EFFECTS OF EXTERNAL TESTING ON CLASSROOM PRACTICES

Sonia Ben Jaafar

Ontario Institute for Studies in Education at the University of Toronto  
sjaafar@oise.utoronto.ca

The centralization of curriculum via the creation and measurement of standards offers a promise of accountability for the work that is done in schools. Accordingly, the Ontario government introduced a ninth grade assessment in mathematics aligned with the Ministry of Education curriculum guidelines. The expectation is that teachers will align their classroom practices with the policy to a greater degree as a result of the pressure of the impending test. The premise, which has limited empirical evidence, assumes that external testing can alter classroom practices. The results of this comparative case study indicate that external testing has a limited influence on teacher classroom practices.

### Background and Purpose

The Ontario government introduced a Grade 9 Mathematics assessment designed to reflect the new curriculum which values student understanding and concept building via investigation, experimentation, and their ability to reason using multiple strategies and representations (Ontario-Ministry-of-Education, 1999). Consequently, we should observe teaching strategies that foster constructivist mathematical learning behaviors. The Ministry's expectation in aligning the assessment to the curriculum guidelines (EQAO, 2001) is that teachers will adjust their classroom practices to enhance the match to the documents because of the pressure of the impending tests. The supporting premise is that assessments have great potential to alter classroom practices. However, the limited studies that have empirically investigated the effects of testing on classroom practices by collaborating observational data with teacher interviews (see Cimbricz, 2002) have contradictory claims. Consequently, irrespective of the prevalent use of testing as an agent of change in schools, the collective claims from relevant studies offer inconclusive results. This study attempts to illuminate the relationship between changing classroom practices and testing through a comparative case study of two mathematics teachers.

### Method and Results

The teachers were teaching both ninth and tenth grade mathematics courses in the same large urban secondary school in Toronto. Both courses received a new curriculum within the last three years, but only the ninth grade had an external assessment introduced last year. Hence, comparing the classroom practices in the two courses offers an opportunity to discern if classroom practices change when implementing a new curriculum in the presence of an external test. Government documents, student work, six guided classroom observations followed by unstructured post-observational

interviews for each class, and three one-hour semi-structured interviews comprised the data. The data was analyzed using an opportunity to learn (Wang 1998) framework whose specifications were established via the document analysis, and validity was established through triangulating the results and performing a member's check.

The most influential factor on classroom practices was departmental policy, which promoted the belief that if the entire content was delivered, the students would succeed on the external assessment. Accordingly, teacher efforts were focused on a timely delivery of the syllabus, which highlighted a perceived time constraint. Teacher reaction to this time restriction was to consciously employ conventional instruction that does not match the exploratory teaching strategies promoted in the Ministry guides. However, the test's effect on course pacing may be limited, as the scheduled lessons for the assessment dates was a series of review classes to prepare for the internal departmental exam. Hence, there is no evidence demonstrating a particular impact on classroom practices from the mandated external assessment.

# Beliefs

## TEACHERS' GOALS: SPRINGBOARDS OR CONSTRAINTS

Bridget Arvold  
University of Illinois at Urbana/Champaign  
arvold@uiuc.edu

Although Piaget's definition of learning includes the mention of goals, a participant's goals are often overlooked in teacher education research efforts. In response to research findings that have alluded to teachers' goals as influential factors in their professional development, I have extended the study of teachers' beliefs and orientations toward knowing to include the study of teachers' goals. I designed this study of secondary novice mathematics teachers' goals to determine whether or not relationships among a teacher's goals might lead to identification of overarching goals, from which, along with core beliefs and orientations toward knowing, I could represent a coherent model of a teacher's actions in relation to her beliefs. Three participants participated throughout their teacher education program and first year of teaching. The emergence of overarching goals related to respect, the politics of schooling, and mathematical inquiry provided the fabric that linked these novice teachers' beliefs and actions.

The view of learning as a response to perturbation that an individual generates in relation to a *goal* (Piaget, 1970; von Glasersfeld, 1995) set the stage for this study of three novice teachers' goals in relation to their process of becoming secondary mathematics teachers. Erffmeyer & Martray (1988) noted the contextual importance of goals as well as the perceived difficulty of achieving goals within contexts. Research findings related to the professional development of secondary mathematics teachers include discussion of teachers' goals (Helms, 1989; McGalliard, 1983; Owens, 1987; Thompson, 1982) and suggest further research in this area. Former research on teachers' beliefs and their orientations toward knowing have shed light on influential forces in the professional growth process of teachers (Cooney, Shealy, & Arvold, 1998), and this research adds yet another dimension to further our understanding.

By investigating the goals that are core to one's identity, namely those that are part of one's embedded tradition (MacIntyre, 1981, 1988), I learned that a teacher's goals may also serve to safeguard identity and provide refuge from conflicting messages (Arvold, 1998). As the foundation upon which one attends to, interprets, and interacts with the rich social structure that defines one's world, embedded tradition is unique to each individual. Consideration of goals as integral components of embedded tradition and the exploration of the relationships among goals, beliefs, and orientations toward knowing in light of philosophies of mathematics teaching (Ernest, 1991) may help explain the challenges that are associated with reform-oriented mathematics teacher education programs. I designed this study of novice teachers' goals to determine whether or not relationships among a teacher's goals might lead to identification of overarching goals, which, along with core beliefs and orientations toward knowing, would help represent a coherent representation of a teachers' actions in relation to her

beliefs. Skott (1999) explained perceived inconsistencies between a teacher's beliefs and actions through the multiple motives of a teacher, whereas I am investigating the possibility of an underlying structure that supports the coherent nature of a teacher's beliefs and actions. A matrix of overarching goals, beliefs, orientations, and responsive actions captures dominant features that contributed to a coherent representation of beliefs and actions for each of the participants and augments the discussion in this report. (See Appendix A.)

The expert/novice research revealed profound differences among teachers. Leinhardt (1987) identified a transparent system of goals that supported the fluidity of interconnections within and among lessons of experts but only ambiguous systems of goals and fragmented lesson structures associated with the lessons of novices. In several other studies the process or product nature of goals was highlighted. As students learned to read, the "read to learn" or process-oriented groups produced higher reading skill scores than the "read to answer question" or product-oriented groups (Schunk and Rice, 1989). Students with a goal of learning how to solve problems rather than a goal of completion, experienced higher self-efficacy ratings as well (Schunk, 1996). These findings led me to Ames' work (1992). According to Ames, a mastery goal orientation is based upon goals that motivate a search for personal understanding or a process, whereas a performance goal orientation is based upon goals that motivate achievement and recognition or a product. I, like Kloosterman (1996), used this framework in my analysis of goals. Although Kloosterman noted that students often express both performance and mastery goal orientations, he also found that students' overall performance goal orientations most often related to their concern about their teachers' views of them as mathematics learners. His research led me to believe that overall goal orientations were related to orientations toward knowing and the deeply rooted embedded traditions that constrain or serve as springboards for growth (MacIntyre, 1981, 1988).

I assumed that the nature of most goals was dynamic and responsive to many influences including personal interests, social interactions, and context. I was most interested in identifying the goals that were less dynamic, that related to other deeply set embedded traditions, and that acted as a foundation through which the process of becoming a mathematics teacher could be interpreted and illuminated. I focused on the research question: What are the goals that are part of the embedded traditions of the participants and how are they related to their beliefs and ways of knowing and to the process of becoming a mathematics teacher?

### **Research Design**

This case study was an outgrowth of a project entitled Research and Development Initiatives Applied to Teacher Education (See endnote.). The primary purpose was to reason toward hypotheses (Glaser & Strauss, 1967; Patton, 1980) and illuminate the process of becoming a mathematics teacher through the study of teachers' goals and goal orientations (Ames, 1992) in relation to embedded tradition (MacIntyre, 1988).

An interactionist perspective (Blumer, 1969) grounded the study and guided data collection methods. Theories of belief structures (Green, 1971), orientations toward knowing (Belenky, Clinchy, Goldberger and Tarule, 1986), and mathematics teaching philosophies (Ernest, 1991) guided analyses. The interdisciplinary theoretical foundation of the study supported my search for connections and relationships among goals, beliefs, and orientations toward knowing.

The interpretive mode of inquiry relied primarily upon patterns of discussion initiated by the participants (Lee & Yarger, 1996) and their introduction to sensitizing rather than definitive concepts (Blumer, 1969). Data were collected almost daily throughout the 12-month preservice teacher education program and monthly during the first year of teaching. Primary data sources included focus surveys with follow-up interviews, individual and group interviews, pre- and post- observation interviews, and observation fieldnotes. Triangulation with respect to responses to specific questions, unsolicited mention of goals, choice of projects and foci of independent personal pursuits, and researcher observations of and participant explanation of instruction assisted in determining each participant's goals. Constant comparative analysis (Glaser & Strauss, 1967) supported the reiterative coding process. Predetermined coding of beliefs, orientations toward knowing, and goals, led to beliefs about the nature of mathematics and orientations toward knowing mathematics. Emergent goal-oriented themes included tradition, respect, policy issues, and mathematical inquiry.

Three of the seven volunteers who participated in the first year of the study secured teaching positions immediately after graduation and thus were able to participate throughout their first year of teaching. Novice teachers Monica, Cheryl, and Alice (pseudonyms) were among a cohort of 15 preservice teachers who entered the secondary mathematics teacher education program at the start of their final year of full time university undergraduate study at a large southern university. Each was dedicated to a teaching career but with somewhat different goals in mind. The study of their goals in relation to their family backgrounds, experiences immediately prior to entry, in the program, and while student teaching, synthesizing, and teaching provide stories which illuminate the embedded traditions of each and the coherence among goals, beliefs, and actions. In this brief report, I include greater depth into Monica's story, and a glimpse into the stories of Cheryl and Alice.

### **Monica's Story**

Monica was the middle child of a small rural farming community in the south. She planned to return to her home community as a teacher and active member of her church community. Immediately prior to entry in the program, she received a full scholarship from the state and the top mathematics award from her school. Both were based upon outstanding performance in her studies.

Monica described her ultimate goal as being a respected member of her home community. She described how she wanted her students to walk away from the school

at the end of a year and look back to the school and comment to each other, "She really made a difference in my life." She offered no explanation of how she might come to make such a difference. She often mentioned how she strove to be a good student and reveled in being known as "the A student." She consistently described a good student as one who follows the directives of the teacher and models the teacher's behavior, even so far as to "know the mathematics just like the professor does."

Upon entry into the teacher education program, she continued her excellent performance in her concurrent mathematics classes. Because of her religious views she stayed away from social activities that involved alcohol and instead spent most evenings studying mathematics. She practiced being a good role model for others. She had not contemplated what the teacher education program would entail. She responded to the unfamiliar discussion and activity-oriented environment in her special way. She remained silent unless called upon by a professor. She seldom entered into discussion even during small group investigations. Instead she worked independently and shared her results and solution strategy only when asked to do so. She preferred highly structured directives and she followed them precisely. Ideas presented in her written and oral responses mirrored the ideas her professors had shared or the literature she had read. The multiplistic ideas presented in her teacher education classes were interpreted through her personal lenses. For example, when asked to use an alternative method to solve a system of equations, she obeyed and then explained that it was good to know alternative methods in case a student inquired, but then added that she preferred to use the correct method.

During Monica's earliest field experiences, she focused on the positive teacher-student relationship that enabled the teacher to help students individually and encouraged the respect of students. In subsequent experiences, she was overwhelmed by students' disrespect for teachers and their lack of interest in learning. In a team teaching field experience she chose to study her segment on reflections and plan the day-2 lesson independently. After the activity-filled first day introduction to transformations, her lecture on finding the coordinates of reflective images confused the high school geometry students as well as her team members. Ignorant of what had gone wrong she opted to take an observer role during the remainder of the two weeks.

Monica entered student teaching apprehensively, was unaccustomed to the non-directive approach of her cooperating teacher and still amazed by the disrespectful nature of the students. Monica associated disrespectful behavior with poor family backgrounds and former life experiences, rather than relating it to the present environment or the teacher-student relationship. Monica chose to focus on acquiring record-keeping skills and on tutoring students who cared enough to come for help after school. When university-related observation was scheduled, she attempted to engage the students in a reform activity. Post-observation interviews revealed that she lacked an understanding of the purpose of the reform activities she introduced. In one case for

instance, an activity she found in the margins of her textbook had great potential for promoting mathematical communication, if only she had facilitated student discussion instead of quietly sitting at her desk. She was disappointed that she had not learned how to teach these unmotivated students during her experience and panicked after learning that she would be teaching a number of general mathematics and pre-algebra classes during her first year as teacher in her home community.

During the following synthesis class, Monica was determined to gain knowledge of how to teach these lower level students. The absence of a professor as an authority figure and her growing knowledge of classmates' rich student teaching experiences motivated her to turn to classmates for expert advice. She seemed transformed. She chose readings pertaining to motivation, joined her classmates in critiquing various methods, and shared her personal analyses openly. She formed friendly relationships with several classmates and socialized with them. She completed two full weeks of plans for each of her three classes. She felt well prepared for teaching and was excited to begin. Her renewed confidence was bolstered by departmental recognition as the program graduate with the most potential.

Monica struggled during her first year of teaching. During the first week of teaching, Monica introduced angles by using various golf clubs to demonstrate the angle that determined the flight of a golf ball. She became flustered when students responded with questions about the angle's effect on the hook of the ball. In their excitement students had scurried to her desk to see the golf clubs. The noise level rose significantly and Monica grew anxious and directed students to their desks and instructed them to focus on the pictures of angles in their textbooks and complete the exercises in the book. She needed to be in control. She tried to facilitate another planned activity the next week but again grew anxious and abruptly stopped the activity. She reverted to teaching in the way she was taught, namely teacher lecture followed by student seatwork. She rationalized that this conventional method had worked for ages. When students begged for more activities, she told them that they had not shown proper appreciation for all the time and effort that she had put forth to design the activities. She insisted upon their respect first but she was never satisfied. Worksheets and textbook exercises filled the remainder of the block schedule's semester long course and the students provoked her constantly. Teachers who recognized her struggle offered assistance but Monica refused their help. The majority of the students failed the course but a fellow teacher assured Monica that her failure rate was typical. Monica seemed unconcerned. Since teaching had drained her energy and enthusiasm, she finally accepted the advice of her fiancé, also a first year teacher, and decided to put a strict behavior policy into effect the second semester but student behavior remained the same. Only Monica's second semester calculus class of 5 male students provided her with a sense of satisfaction as a teacher during her first year of teaching.

Obviously, this overview provides only a glimpse into the process through which Monica was becoming a teacher but it highlights how her goal for gaining respect

through being the good student did not transfer into a reform-minded notion of being a good teacher. Only in the absence of an authority figure had she opened herself to the support of colleagues and dare to share her unique voice. She may not have realized that through her actions in the synthesis class, she had gained respect and that she would continue to be respected if she accepted assistance from others. She never understood becoming a teacher as a process and instead expected to know all she should know to be a teacher during her first year. She reverted to isolation from the mathematics education community only two weeks into her teaching career. Monica's goal was easy to identify because her mention of being respected, especially by students, permeated her dialogue from the first interview through the last. She only initiated discussion of mathematics once during the two-year study and seldom mentioned key aspects of teaching and learning. Her orientation toward received knowing transferred to her expectations of her students. Through her lens of embedded tradition she interpreted the teacher education focus on empowering students by creating opportunities for higher order thinking quite differently than intended. Her focus on responses that reiterated what an authority had told her or what she had told her students was connected to her notion of respect. Classroom observations provided evidence that she connected extraneous comments or questions with disrespect. Unfortunately the study's interpretive mode of inquiry allowed Monica to avoid discussions of mathematics, learning, assessment, and teaching methods. When I asked questions about these topics within the context of her teaching, she responded by diverting the discussion to her students' lack of respect or to comments from other teachers about these students and their unfortunate circumstances. This diversion was consistent throughout the study as was her self-centered orientation.

### Cheryl's Story

Cheryl grew up in a small community, and as a teenager she began to question the blind faith of her religious family. She was intrigued by the nature of communities and their influence. Her childhood desire to become a teacher transformed into the desire to not only teach in a classroom but also promote quality education for *all*. She entered college immediately after high school, but her journey toward certification continued for 17 years. She married after her first year of college study and became a mother two years and again four years afterward. She responded to the annual or biannual transfers of her husband by becoming active in her respective communities, especially school communities. She continued part time study until she became a full time student and entered this study. Although her college mathematics performance was average, she enjoyed the structure within and the mystique surrounding mathematics. She deemed skill mastery, inquiry, and applications as fundamental components of all mathematics curricula. Her work experiences as a teacher's aid in elementary and special education classrooms and her children's public school experiences enhanced her view of teaching and education.

Upon entry into the program, Cheryl's stated goal was to prepare for a career in teaching. She expected to share what she had learned through experience to better prepare herself and others for teaching. She expected to learn how to work with and within a system as well as a classroom, and she believed that her study of mathematics was complete. Disappointment reigned as her years of mathematics study proved to be insufficient preparation for the mathematics investigations that were integrated into the first teacher education class. Her enthusiasm plummeted during the 5-week study of functions, yet she continued to interject related stories. She felt alienated from her professor and classmates when their interest in her stories waned, but she continued to share her perspectives and the experiential evidence that supported them. Her classmates referred to her as the voice of experience.

Although Cheryl embraced the vision of NCTM standards, a healthy skepticism accompanied her study of reform-oriented teaching methods. She felt confident in her ability to teach individuals and small groups of students and was anxious to learn how to facilitate learning for large groups of students. She showed a great interest in moving beyond the design of activities and a desire to explore elements of classroom and school environments that support or deny access to learning for all. Her early field experiences provided her with opportunities for personal exploration but constraining factors overwhelmed her as she tried to satisfy the expectations of others. She felt constrained by a system that failed to provide the space, technology, and support necessary for quality teaching.

She set clear goals for student teaching. She planned to provide the students with the best instruction she could while she learned to work within the system and possibly convince her cooperating teacher of the benefits of technology. Although she experienced tension working within the system throughout her student teaching experience, she believed that she expanded her teaching expertise to teaching large groups of students. Fieldnotes verify her effectiveness as she facilitated probability experiments and exploration of graphical representations.

Experiences during her first year of teaching were varied. She was highly respected by teachers in her department and worked with them for the professional growth of all. Her goal was to seek a balance of school and home life and begin to affect positive change in education in general. Her school system awarded her time and funding to pursue her interest by attending conferences and workshops in the Spring of her first year of teaching. She also experienced obstacles that threatened her commitment to teaching. A student threatened her with bodily harm and although the student was suspended from school, the administration would not remove the student from her class and the return of the student caused her profound anxiety. The year ended on a sad note as well. An administrator asked her to change a grade of a student in response to the parents' request. She had entered into contracts with the student several times during the school year and the student had not honored the contract. After many meetings and

with an unclear conscience, she reluctantly acquiesced. Although individual learning was of great importance to her throughout the study, Cheryl most often initiated discussion about how to interpret the actions of, manage, and teach groups of students. She also initiated discussion of the inner working of school systems. She enjoyed coming to understand the dynamics of classrooms and school communities. She did focus on student learning and teaching but the politics of the classroom and the school were of major importance.

### **Alice's Story**

Like many of her teacher education classmates, Alice was from a suburban community in which both parents worked. Unlike classmates who openly shared their Christian philosophies, she lacked religious commitment and was torn between the Jewish and Christian beliefs of her parents. While in high school, she experienced the divorce of her parents. In response, she sought the companionship of a new group of friends and although she did not abandon her commitment to learning in school, she encountered a drug and music culture that was not supportive of formal education. As she assisted her new boyfriend through difficult times, she gained a new perspective of education. She became determined to provide all students the opportunity for empowerment

Alice's goal upon entry to the program was to learn how to help students learn to think for themselves. She focused on mathematical thinking. Although the message promoted in the teacher education program emphasized individual sense making, she perceived the climate in her education class as counter to the message. She quietly studied students in her class who simply followed the path set out for them. She also focused attention on her overarching goal of promoting inquiry and used her creativity to design motivational activities that would encourage mathematical thinking. During early field experiences she facilitated mathematical inquiry and students responded quite enthusiastically. During her student teaching, she began to follow the mathematical tangents initiated by students and their multiple ways of sense making.

During Alice's first year of teaching in a rather affluent suburban school, she expanded upon her methods and became quite adept at co-creating a learning environment in which problem solving and sharing of multiple strategies were the norm. Unfortunately parents again caused turmoil in her life. Monica had responded to a student's question about an alternative solution method with, "I don't know if this strategy will work. Let me study it tonight and we'll discuss it tomorrow." I had recorded a few student expressions of "gotcha" in my field notes and was alerted to a possible underlying attempt to discredit the first year teacher. Indeed, the parents contacted the head of the mathematics department and stated their displeasure with having their children in a classroom with a first year teacher who obviously did not know her mathematics.

Fortunately Alice had already gained the respect of her peers and department head for her in-depth knowledge of mathematics. She had asked her fellow teachers about how they introduced functions and after learning that they simply stated the definition, she shared a few of the ideas she had learned in her teacher education class. The head of the department subsequently asked her to conduct a more in-depth workshop for all the teachers. Nonetheless, the lack of parental support for her passionate attempts to encourage students to become mathematical inquirers was disheartening for her. With the support of her colleagues, she became more resolute in her goal of teaching students to think for themselves. During most research interviews, she initiated mathematical problem solving activities. She discussed the different student approaches to the problems only after I had an opportunity to engage fully in the mathematics. She was particularly enamored with questions students brought to her. Her favorite was determining the appropriate size and placement of audio speakers in the trunk of a car. Her student-centered and inquiry-directed orientation dominated her experiences throughout the study.

### Synthesis and Implications

The embedded goals of three preservice teachers led them to attend to different aspects of their teacher education program and use their embedded traditions as constraints or springboards. Monica was able to work outside her embedded traditions for a short time but her embedded tradition simply could not support activity-oriented teaching in the classroom. Performance goals and isolationist tendencies (Cooney et al., 1998) constrained her professional growth as a mathematics teacher. On the other hand, Cheryl and Alice's mastery goal orientations and commitment to the life-long nature of the process of becoming a teacher more often served as springboards from embedded tradition despite obstacles. The goals of learning the politics of schooling and promoting mathematical inquiry resembled the fluid and interconnected goals of expert teachers whereas the fragmentation associated with novice lessons was more aligned with the goal of respect that lacked a pathway toward it.

This research informs research and teacher education practices in many ways. The inconsistencies reported in the research may not be inconsistencies at all. We, as teacher educators, need to practice what we preach and connect to student interests that are much more profound than simply becoming a mathematics teacher. A program that recognizes goals within embedded tradition might have offered Cheryl and Alice greater opportunity for professional growth and offered Monica a pathway to use her embedded tradition as a springboard. Goal setting activities might not only inform instructors but also assist teachers in building pathways toward their goals. My current research findings support this conjecture as well as the empowering nature of action research. Novice teachers need not spend their first year in survival mode. They have much to offer their students, colleagues, and themselves if they learn how to springboard from their traditions to grow professionally.

Relationships between Overarching Goals and Beliefs, Orientations toward Knowing, and Practices

## IMPLEMENTING STANDARDS-BASED MATHEMATICS CURRICULA IN THE MIDDLE GRADES

Cynthia W. Langrall  
Illinois State University  
langrall@ilstu.edu

Jane O. Swafford

mascran2@ilstu.edu

A series of case studies was undertaken to better understand the process of implementing Standards-based middle school mathematics curricula. Based on data collected from 4 school districts over 3 years, the findings of this study indicate that there are identifiable factors that can support curriculum implementation or, in their absence, can impede the implementation process. Five broad factors were identified across the 4 sites: (a) a plan for implementation of the materials; (b) district- and building-level leadership and support; (c) ongoing professional development aimed at the changing needs of teachers; (d) teachers' philosophical agreement or compatibility with the curriculum; and (e) curriculum alignment with state standards and tests. At the end of 3 years, we found stable implementation in only one district; in each of the other three districts conditions threatened the success of the implementation.

In response to the need for curriculum materials that reflect and support the philosophy and pedagogy of the NCTM Curriculum and Evaluation Standards (1989), the National Science Foundation funded a series of curriculum development projects that subsequently published what have come to be known as Standards-based curricula. At the middle school level, five core curriculum programs are currently on the market: *Connected Mathematics Project*, *Mathematics in Context*, *MathScape*, *MATH Themes*, and *Pathways to Algebra and Geometry*. These programs have become recognized as legitimate alternatives to traditional mathematics textbooks and are being adopted in school districts across the country.

There are vast differences in the content, and to an even greater extent the pedagogy reflected in Standards-based materials, and that of traditional mathematics textbooks. According to St. John, Heenan, Houghton, and Tambe (2001), these innovative curricula "demand new modes of instruction, require more expertise, resources, time, and effort to implement" (p. 3). Such demands on instructional practice can be overwhelming to teachers and change should be cultivated and supported through professional development (Manouchehri & Goodman, 2000). The research literature has begun to identify factors that contribute to the successful implementation of Standards-based curricula, as well as factors that present obstacles to implementation. Factors that support the implementation process include: the establishment of collaborative relationships between school districts, institutes of higher education, and business and scientific communities (Bay, 1999; Batchelder, 1998; St. John & Pratt, 1997); strong alignment between the curriculum and state policies (Batchelder, 1998; St. John & Pratt); and district allocation of resources (Batchelder, 1998; St. John &

Pratt, 1997). Obstacles to implementation are often created by a teachers' superficial understanding of mathematics reform (Batchelder, 1998; Haug, 2000), negative student reaction and parental perception (Bay, 1999; Reys, Reys, Barnes, Beem, & Papick, 1998), and emphasis on high stakes state and district assessments (Batchelder, 1998; Bay, 1999; Haug, 2000).

Our study builds upon and extends this research by systematically examining the process of district-wide implementation of Standards-based middle school mathematics curricula. More specifically, three research questions were investigated: (a) To what extent are the curricula being implemented? (b) What are the supports and barriers to implementing the curricula? and (c) What is the impact of implementing the curricula on students and teachers?

### Method

When this study was initiated in the fall of 1998, only four of the middle school curricula were published commercially: *Connected Mathematics Project*, *Mathematics in Context*, *MathScape*, and *MATH Thematics*. Although *Pathways to Algebra and Geometry* was later published and included in our study, this paper reports only on the findings related to the other four curriculum projects.

### Case Study Sites

Four school districts, each in the process of implementing one of the NSF-funded curriculum programs, were identified for case study analysis. In selecting case study districts, we attempted to include sites from different parts of the country and to represent a variety of demographics. Only sites that reported district-wide adoption and implementation were selected for participation in the study. For each curriculum project, one case study site was selected from a list of school districts provided by the curriculum developer. A brief description of each site is presented below.

#### Arnold Community Schools.

Arnold is a predominately middle-class Midwestern community of about 60,000 people. The population is about 85% white, 14% African American, and 1% other ethnic groups. The school district serves approximately 11,000 students in 22 schools: 16 elementary, 3 middle, and 3 high schools. Until recently, the economy in Arnold was dominated by industry and accommodated an unskilled or semi-skilled workforce. However, the economy has dramatically changed and the need for unskilled laborers has diminished. The community has realized the need to prepare students for an information economy and has focused on revitalizing and improving the educational system. The school district began full implementation of *MathThematics* during the 1998-99 academic year in grades 6 through 8, with the exception of the 8<sup>th</sup>-grade Algebra 1 class. Standards-based curricula were not adopted at the elementary or secondary levels.

### **Harrison County Public Schools.**

Harrison County surrounds a large city located on the east coast. Its communities include affluent suburbs in the western part of the county to rural areas in the east. There are also urban neighborhoods closer to the city limits, in the center of the county. The school district serves 40,000 students in 39 elementary, 9 middle, and 8 high schools. The student population is 62% white, 33% African American, 3% Asian, 1% Hispanic, with the remainder of students from other ethnic backgrounds. During the 1998-99 academic year, the *Mathematics in Context* curriculum was being implemented in all middle schools except the alternative school. We came to learn, however, that use of the materials was optional in all but the advanced learner classes. Hence, rather than a full adoption and implementation, *Mathematics in Context* was one of two adopted texts; the other being a traditional middle school series. Standards-based curricula were not being used at either the elementary or secondary levels.

### **Montgomery Public Schools.**

Montgomery is a large urban city in the Midwest. The school district serves about 102,000 students in 114 elementary schools (10 of which are K-8 buildings), 22 middle schools, and 18 high schools. The student population is 61% African American, 20% white, 13% Hispanic, 4% Asian, and 2% other ethnic groups. At the middle school level, 76% of the student qualify for free lunch. As participants in an urban systemic initiative, the district was encouraged to adopt a Standards-based mathematics curriculum. During the 1998-99 school year, the district undertook full implementation of the *Connected Mathematics Project* curriculum in grades 6 – 8 and the Standards-based *Investigations in Number, Data, and Space* in the elementary grades.

### **Valley Springs Unified Schools.**

Valley Springs is a bedroom community for a major metropolitan area on the west coast and is also a small city in its own right with a population of 120,000. The socio-economic status of the community ranges from urban poor to suburban middle class. The school district serves 20,000 students in 17 elementary, 4 middle, and 3 high schools. The school population is 25% African American, 20% Filipino, 20% white, 16% Hispanic and 6% Asian and Pacific Islander. Valley Springs began full implementation of *MathScape* during the 1998-99 academic year in all classes in grades 6 through 8 except the 8<sup>th</sup>-grade Algebra 1 class. The impetus for reform in the middle grades came from the high schools' use of an integrated reform curriculum and piloting one of the Standards-based secondary programs. Also, a Standards-based elementary program, *Trail Blazers*, was adopted at the elementary level.

### **Procedure**

Beginning in the academic year 1998-99 and continuing through May 2002, a series of site visits were conducted in each of the case study districts. This paper will

report on the first three years of that study. During Year 1 of the study, three of the sites were visited on two occasions, while the fourth site received only one visit. In Year 2, all sites were visited once. In Year 3, one site was dropped from the study and the remaining three sites were visited once. Because the purpose of this study was to examine the implementation process within a school district, a different school was targeted for each site visit. Typically, 1.5 days were required to complete a site visit.

During each site visit, interviews were conducted with classroom mathematics teachers, the principal, the lead teacher or building-level math coordinator, and district personnel. The district contact person in each site was interviewed during each visit, thus providing a stable perspective over the three years of the study. Approximately 70 teachers, 11 principals, and 15 different building-level and district personnel were interviewed.

Most interviews were conducted individually, but some were conducted in small groups, usually as grade-level teams. An interview protocol was developed to address the following issues: (a) the extent to which the curriculum materials were being used at each grade level; (b) perceived barriers and supporting structures for implementation as related to the district, principal, teachers, and parents; and (c) the impact of the curriculum on student's achievement, students' disposition, teachers' knowledge, and classroom practices. These issues remained the focus of each interview throughout the three years of the study. All interviews were conducted according to the protocol, but specific follow-up questions were tailored to probe or clarify a particular response.

Most interviews were audio taped, although there were situations where the physical setting was not conducive to taping or teachers were uncomfortable being taped. For all but a few interviews, two researchers were present and they both took written notes throughout the interview. As possible, pertinent artifacts such as locally generated pacing guides, schedules of professional development sessions, and summaries of student achievement data were collected.

### **Data Analysis**

Data analysis was an on-going process that occurred in two phases. In both phases, a data reduction approach (Miles & Huberman, 1994) was used to discern patterns or trends in the data. Given the self-report nature of the data, interviews with principals and other building-level and district personnel were used to triangulate the teachers' perceptions of the implementation process. During the first phase of analysis, interview data from each site visit were analyzed in terms of the three research foci: extent of implementation, supports and barriers to implementation, and impact of implementation on students and teachers. Following each site visit, one researcher reviewed her written notes and the interview tapes to organize and synthesize the data around the three research foci. Data tables and narrative summaries were constructed to present the findings. These tables and summaries were then examined by one of the other researchers, using her notes (and if necessary, further review of the tapes) as a

check. Any discrepancies in interpretation were discussed and resolved. This process was followed for each of the site visits and resulted in the identification of *within-case* trends pertaining to the implementation process as perceived and enacted at each school.

In the second phase of analysis, trends *across* the four case study sites were examined. For each year of site visits the data tables and narrative summaries for each site were analyzed and patterns across the four sites were identified in terms of the three research foci. Cross-case summaries were developed to characterize the process of implementing Standards-based curricula at each point of implementation (i.e., year 1, year 2, year 3). These yearly cross-case summaries were also analyzed to discern generalities across the three years of implementation.

### Findings

This section is organized according to the three research foci. General findings pertaining to the extent of implementation, support structures and barriers to implementation, and the impact on students and teachers are presented across the four case study sites.

#### Extent of Implementation

Given our criteria for selecting sites that had initiated district-wide adoption and implementation, it is not surprising that the majority of teachers we interviewed reported using their respective curriculum materials as the basis of their instruction. That is, these teachers reported using the materials at least 40% of the time, and most teachers indicated major use at more than 60% of the time. The fidelity of implementation, however, varied greatly within districts by schools, teachers, and grade levels.

The most common finding across sites was that almost all teachers, even those who reported using the materials “fully,” supplemented the curriculum with extra review and practice activities. For some teachers the supplementing was extensive, for others it was only minimal. Many teachers commented that students entered their classrooms without the prerequisite skills and concepts assumed by the curriculum. These teachers believed it was necessary to develop students’ skills prior to using the curriculum materials and thus drew upon activities they had used previously or found in other resources. Some teachers did not believe the curriculum materials devoted enough time to allow students to fully understand a particular topic (e.g., fractions, percents, integers) and supplemented units or modules with extra activities and worksheets. Similarly, teachers reported that the curriculum materials did not provide enough practice for a particular skill or concept within a lesson. At all sites, teachers provided extra practice and even specific instruction beyond the scope of the curriculum materials in preparation for state and standardized tests.

In all districts, there were some teachers who failed to implement the adopted curriculum or used it only rarely. Often, these were teachers who were new to the district

and had not received professional development related to the curriculum or who were long-term substitutes. This was especially evident in Valley Springs where there was a shortage of certified teachers, particularly at grade 6. In Arnold, the dissenters were typically grade 8 teachers who did not believe the materials were appropriate for their students. According to one teacher, "These students need fundamental drill work." In Montgomery, the implementation was weakest in the two magnet schools where teachers openly refused to use the materials because they believed their gifted students needed a "more challenging" curriculum.

By the third year of implementation there was evidence that the Standards-based curricula in three of these school districts were struggling for survival. In Arnold, there was only one 8<sup>th</sup>-grade teacher fully implementing the curriculum. Most of the other grade 8 teachers openly opposed to the reform philosophy and actively pursued a skills development curriculum using worksheets and other materials. This was beginning to create a negative influence on teachers at the other grade levels. The Harrison district was dropped from the study in Year 3 because we learned that the materials were rarely being used, even in the advanced learner classes, and that the district no longer planned to extend the use of the materials to non-advanced classes. Although the district personnel in Valley Springs perceived the implementation as going well, there was concern about the fate of the curriculum because of a state mandate that only approved textbooks could be purchased and *MathScape* was not on the state textbook adoption list. Montgomery was the only district in which the curriculum implementation appeared to be relatively stable. The district mathematics coordinator reported that about 90-95% of the teachers were actively using the curriculum, albeit at different levels of implementation.

### **Supportive Structures and Barriers to Implementation**

A variety of factors that either supported implementation, or in their absence created barriers, were identified for each case study site. Five broad factors were identified across the four sites: (a) a plan for implementation of the materials; (b) ongoing professional development aimed at the changing needs of teachers; (c) district- and building-level leadership and support; (d) teachers' philosophical agreement or compatibility with the curriculum; and (e) curriculum alignment with state standards and tests. These factors, some of which were mentioned above with regard to the extent of implementation, are discussed individually although many of the issues are closely related.

#### **Implementation plan.**

To facilitate the implementation process, two districts developed plans for gradually implementing the curriculum at each grade level and one district reorganized the sequence of topics to better match the state standards. In Montgomery, core units for each grade level were identified and a sequencing and pacing guide was developed

to facilitate the phase in of the curriculum over three years. In Year 1 the 6<sup>th</sup>-grade classes used the grade 6 materials, the 7<sup>th</sup>-grade classes used some of both grade 6 and 7 materials, and 8<sup>th</sup>-grade used the grade 7 materials. In Year 2 the 7<sup>th</sup>-grade classes used the grade 7 materials while the 8<sup>th</sup>-grade used some modules from both of grades 7 and 8. In Year 1 the goal at each grade level was to complete 5 units, and by Year 3 it was expected that teachers would complete all of the core units targeted for their grade level. In Valley Springs, a customized sequencing and pacing plan was developed for Year 1 only, on the expectation that teachers would be unable to complete all the units in their first year using the materials. Specific units and lessons at each grade level that closely matched the district's mathematics framework were identified for implementation in Year 1. It was expected that in subsequent years the teachers would increase the number of units covered to include the entire curriculum. Although Harrison County did not develop a plan for the gradual implementation of the curriculum within each grade level, they did reorganize the order of topics within the materials to more closely match the scope and sequence of the state standards.

Almost all of the teachers we interviewed, including those in districts with specified sequencing and pacing plans, reported that they had difficulty completing all of the curriculum modules or units expected by the district. Moreover, this concern continued to be voiced in Year 3, after many of the teachers had been using the materials for two years. In each district few teachers, if any, were able to address all of the required curriculum modules or units. However, teachers in districts with sequencing and pacing plans had an idea of which units could be skipped and which ones should be emphasized. In districts without such guides, individual teachers addressed the materials quite differently, picking and choosing units or lessons within units. In these cases the coherence of the curriculum within and across grade levels was potentially compromised.

### **Professional development.**

All of the teachers we interviewed indicated that professional development was needed beyond the first year of implementation and that it should address the changing needs of teachers, as they became more familiar with the materials. Teachers reported that the most valuable professional development activities were ones conducted by facilitators who had actually taught the materials and who could “walk through” a module and highlight specific lessons, investigations, and problems that should be emphasized and ones that could be skipped.

Teachers also believed it was important for all of their mathematics colleagues to be able to attend workshops. In some schools, principals sent only lead teachers or one teacher per grade level to workshops offered during the school day. The expectation that these teachers would bring information back to share with the rest of the faculty was rarely fulfilled and teachers did not find this approach acceptable. In three of the four districts, teachers expressed concern that attendance at professional development

sessions was voluntary rather than required. Hence, the perception was that teachers who most needed professional development did not take advantage of the opportunities provided. Some teachers, as well as district personnel, felt this had a negative impact on the implementation.

### **Leadership and support.**

The importance of strong administrative leadership and support were considered important factors contributing to the success of the implementation. At the district level, the implementation process was usually spearheaded and managed by key district personnel. These were also the people who coordinated, and often conducted, professional development activities. Principals also provided support in a variety of important ways. They provided the resources and materials needed to implement the curriculum, opportunities for common grade-level planning or department meetings, and release time for teachers to engage in professional development activities.

### **Philosophical agreement.**

The teachers in this study who never, or only rarely, used the Standards-based curricula espoused traditional beliefs about the teaching and learning of mathematics. Essentially, their beliefs about what it means to know and learn mathematics did not match the philosophical perspective of the curricula. The most common of these beliefs was that students should be taught specific concepts and skills prior to engaging in investigations. For these teachers, the mastery of computational procedures was seen as a prerequisite to problem solving. Thus, in their view, the curriculum materials did not provide enough examples and practice problems for students to become proficient in "the basics."

### **Alignment with state standards and tests.**

In each district, a significant factor in choosing to adopt a Standards-based curriculum was the belief that it was closely aligned with state and national standards. More particularly, all of these districts were involved in some aspect of mathematics reform through participation in national or state projects (Arnold and Montgomery) or through the initiatives of the district (Harrison and Valley Springs). District personnel believed that reform efforts would be supported through the use of a Standards-based curriculum.

Over the course of this study, state standards or testing procedures changed in three of the four districts to the extent that the success of the curriculum implementation was threatened. In Valley Springs, as mentioned above, the *MathScape* curriculum was excluded from the state textbook adoption list. There was also a move by the state to require all 8<sup>th</sup>-grade students to take Algebra 1. This mandate prompted the district to consider merging the three-year mathematics program into two. In Harrison County, performance on state assessments and proficiency in meeting the state

standards overshadowed the focus on mathematics reform. This was prompted by the fact that the district led the state in percent of schools meeting state standards. The Superintendent was anxious to maintain that status, thus, extraordinary emphasis was placed on maintaining and increasing test scores. In Arnold, the state standards were significantly revised to increase the number of concepts and skills required at each grade level. For many topics, the organization and sequencing of the curriculum materials no longer matched the standards. Montgomery was the only site where state and district requirements continued, over the course of this study, to be supported through use of the curriculum materials. In fact, district proficiency tests for grades 6 through 8 remained very closely aligned with the *Connected Mathematics Project* curriculum. In many cases assessment items were directly modeled after problems or activities in the curriculum.

### **Impact on Teachers and Students**

#### **Students' disposition toward mathematics.**

Students' reactions to these curricula were mixed. For many, their first experiences were frustrating because of the amount and level of reading required. Also, many students were not accustomed to having to explain their thinking and justify their responses. Nevertheless, teachers reported that most students' attitudes improved as they became more familiar with the materials and knew what to expect. Teachers also reported that students enjoyed the hands-on explorations and discovery activities. Some students showed a greater appreciation for mathematics and expressed more interest in the subject. Teachers also noted an increase in students' abilities to think mathematically to solve problems.

#### **Students' achievement.**

Although most teachers and district personnel indicated that they expected an increase in achievement scores following the implementation, we were unable to document any significant overall growth in these districts. In the third year of implementation, state test scores in Arnold had declined district-wide. In Valley Springs, standardized test scores had remained relatively flat at all grade levels over the three years of this study. In Montgomery the percentage of students meeting grade-level proficiency requirements increased steadily over the three years, but state test scores had not changed significantly overall.

#### **Teachers' knowledge and classroom practice.**

Many of the teachers we interviewed reported that using these curriculum materials had prompted them to think differently about mathematics and sometimes deepened their understanding at a conceptual level. Most teachers, however, reported that the materials had impacted their practice more than their knowledge of mathematics.

For some, the materials complemented and supported the pedagogical approaches they already used. Others recognized changes in their pedagogy such as incorporating more group work, use of manipulatives and calculators, asking for student explanations and justifications, having students share solutions at the overhead, and using journal writing.

### Discussion

The findings of this study support claims in the literature regarding the difficulty of implementing a Standards-based curriculum. In examining the challenges encountered by the teachers in our study, we have identified critical support structures and potential barriers that are pertinent to the implementation of any of the middle school curricula. In essence, teachers need ongoing technical assistance as well as intellectual and emotional support in order to implement these materials successfully. We also found that over time students adapt to the pedagogy of these curricula, and many develop a more positive disposition toward mathematics.

One conclusion that can be drawn from our work is that ultimately, the most significant factor in determining the long-term success of these Standards-based mathematics curricula could be their impact on student achievement in terms of state standards and assessments. The implementation process in each of the districts in this study was influenced in some way by such measures. In three of the districts specific conditions that threatened the success of the implementation were directly connected to new state standards and issues related to student achievement. Even in the one district where the implementation did not appear to be threatened, district personnel were concerned that there had not been greater improvement in state test scores.

There is some evidence in the research literature (Ben-Chaim, Fey, Fitzgerald, Benedetto, & Miller, 1997; Hoover, Zawojewski & Ridgway, 1997; Tetley & DuBose, 1997) that suggests that students using these Standards-based curricula perform as well as students using traditional curricula on traditional achievement measures and even better on measures that account for problem solving and higher-level thinking. Unfortunately, overall achievement gains could not be identified in any of the districts in our study. One reason is that it is difficult to gauge the impact of a curriculum when the faithfulness of implementation varies so greatly from teacher to teacher. The achievement of students from classes with strong implementation could be averaged out by the achievement of students from classes where the implementation is weak. The uneven implementation of curriculum materials highlights how important it is to analyze achievement data, not only by grade level, but also by individual students and teachers. Across a district, student achievement data should be disaggregated by the number of years in high implementation classrooms. This type of analysis could better document the impact of a Standards-based curriculum on student learning. Although Briars and Resnick (2000) have presented a good model for this type of research, access to the required data is not easily obtained. Yet this is exactly the kind of data

school districts need to garner support for these curricula. Over the three years of this study we were unable to obtain the kind of data to produce such an analysis. This is an area of research we will continue to explore and one that should be given top priority by other researchers as well.

## ENTAILMENTS OF THE PROFESSED-ATTRIBUTED DICHOTOMY FOR RESEARCH ON TEACHERS' BELIEFS AND PRACTICES

Natasha M. Speer  
Michigan State University  
nmspeer@msu.edu

In research on teachers' beliefs, a distinction is often made between what teachers state ("professed beliefs") and what is reflected in teachers' practices ("attributed beliefs"). Researchers claim to have found both consistencies and inconsistencies between professed and attributed beliefs. In this paper, I examine methods and research designs typically used in studies of teachers' beliefs. I assert that, in some cases, the perceived discrepancy between professed and attributed beliefs may actually be an artifact of the methods used to collect and analyze relevant data. In particular, I contend that the apparent dichotomy can be the result of a lack of *shared understanding* between teachers and researchers of the meaning of terms used to describe beliefs and practices. Traditional and novel methods are described, a data example is provided to illustrate my claims, and implications for future research are discussed.

### Introduction

Theories, methods, and findings in research are inextricably intertwined. A researcher's theoretical perspective influences and shapes methods used to conduct research. A researcher's methods encapsulate and embody theories. Methods, however, only allow researchers to "see" what those methods provide access to (Schoenfeld, 1992). Theoretical perspectives may also constrain what researchers see in phenomena and what they seek to see, hence shaping findings and developments in theory. These are inherent characteristics of the research enterprise. It seems productive, however, to examine theory, findings, and methods collectively—especially in a developing field such as mathematics education research—to see whether one or more may be potentially shaping how phenomena are examined.

In this paper I examine the use of the dichotomy of professed versus attributed beliefs as it is found in research on teacher's beliefs and practices. Beliefs about mathematics, teaching, learning, and students are often described as either "professed" or "attributed." Professed beliefs are defined as those stated by participants and attributed beliefs are those that researchers infer based on observational or other data. I assert that in some cases differences between professed and attributed beliefs may in fact be the result of a methodological artifact and not an accurate reflection of the nature of the phenomena researchers seek to understand. The use of this construct has influenced the methods used in studies of beliefs and practices and has also shaped the nature of research findings and resulting theories.

This paper begins with a very brief survey of literature on teachers' beliefs and practices. I then describe methods typically used in this area of research (questionnaires/interviews and observations, respectively). In the third section, I

describe the professed versus attributed dichotomy and discuss how, in some cases, perceived inconsistencies may be the result of a lack of *shared understanding* among researchers and teachers about what descriptive terms mean. In the subsequent section, I present alternative data collection methods, based in part on “videoclubs,” designed to address this issue. In the fifth section, I present a data example to illustrate my points and then conclude with a general discussion and potential implications.

### **What Is Known About Teacher Beliefs And Practices**

#### **Overview**

In the 1960s and early 1970s, research on teachers was strongly influenced by behaviorist views about teaching and learning. The objective of much of the work was to “describe teaching in terms of sequences of behavior, and then to investigate the relationship of that behavior to children’s learning” (Calderhead, 1996, p. 709). The development of information processing theory and other aspects of cognitive science shifted studies of teaching away from behaviorist perspectives. The process-product paradigm that characterized the earlier behaviorist work was superseded by other approaches that focused on teachers’ thinking and decision making (Thompson, 1992). More recent research focuses more extensively on cognition and contexts of learning. Instead of examining only teachers’ behaviors, this recent work addresses teachers’ perceptions, thinking, judgments, reflections, evaluations, and routines (Calderhead, 1996). This research agenda has developed to include investigations of the knowledge and beliefs behind teachers’ practices.

From findings in teacher cognition and other sub-fields of educational research, we know there are many factors that influence the decisions and practices of teachers (Borko & Putnam, 1996; Clark & Peterson, 1986). A teacher’s subject matter knowledge, pedagogical knowledge, and pedagogical content knowledge are all important influences on teaching practices—so too are the curriculum in use, the teacher’s goals, and myriad other social and contextual factors. Research suggests, however, that beliefs are one of the significant forces affecting teaching (Calderhead, 1996; Richardson, 1996; Thompson, 1992).

Beliefs have been described as a “messy construct” with different interpretations and meanings (Nespor, 1987; Pajares, 1992). Current definitions of beliefs found in the mathematics education literature, however, focus primarily on how teachers think about the nature of mathematics, teaching, learning, and students. In this context, beliefs are defined as conceptions, personal ideologies, worldviews, and values that shape practice and orient knowledge (Ernest, 1989; Pajares, 1992; Thompson, 1984; Thompson, 1985; Thompson, 1992).

Influenced by their own experiences as students as well as more formal teacher preparation, teachers form beliefs about what it means to teach, how it is one learns, what the nature of math is, and what students are and should be like. Researchers con-

tend that “beliefs are instrumental in defining tasks and selecting the cognitive tools with which to interpret, plan, and make decisions regarding such tasks; hence they play a critical role in defining behavior and organizing knowledge and information” (Pajares, 1992, p. 325). Beliefs appear to be, in essence, factors that shape decisions teachers make about what knowledge is relevant, what teaching routines are appropriate, what goals should be accomplished, and what the important features are of the social context of the classroom. Beliefs shape teachers’ practices and hence the learning experiences of students. Teachers’ beliefs are therefore vital determinants of the type of understanding of mathematics that students have the opportunity to acquire. As a consequence, examinations into the description, nature, and role of beliefs in teachers’ practices are an important and rich arena for research.

### **Belief Categorization and Classification**

Researchers have delineated categories of beliefs (Ernest, 1985; 1988; 1989; Kuhs & Ball, 1986; Lerman, 1990; Prawat, 1992; Skemp, 1978). Often-sited categories include beliefs about mathematics, teaching, learning, students, and related subcategories. For beliefs about mathematics, some researchers have appropriated categorization schemes from philosophy of mathematics. For example, Ernest (1989) proposed different views of mathematics: problem solving, Platonist, and instrumentalist. The problem-solving view takes mathematics to be a “continually expanding field of human inquiry,” where as in the “Platonist” view mathematics is a unified, static body of knowledge that is discovered, not created. In the “instrumentalist” view, mathematics is a collection of useful unrelated facts, rules, and skills. Other categorizations are derived from different views of the nature of mathematical knowledge. Lerman (1990), for example, sorts beliefs into two categories: “absolutist” and “fallibilist” views of mathematics. Skemp (1978) says there is “relational understanding” of mathematics (knowing both what to do and why) and “instrumental understanding,” which he describes as “rules without reasons.”

Beliefs about teaching and learning have also been categorized. For example, Kuhs and Ball (1986) summarized four views of teaching and learning. One is described as “learner-focused,” while another is characterized as “classroom-focused.” Two others are closely tied to content, with one emphasizing conceptual understanding and the other centering on performance of skills.

### **Relationships Between Teacher’s Beliefs and Practices**

Once categorized by researchers, teacher’s beliefs are sometimes compared with observations of practices. Research has documented that the beliefs teachers hold related to mathematics, teaching, students, and learning play out in interesting ways in their practices. In some cases, researchers found that professed beliefs were consistent with what was reflected in observations of classroom practice. For example, Thompson (1985) described a teacher named Kay who viewed mathematics as a “subject of

ideas and mental processes rather than a subject of facts" (p. 288). She also viewed the study of mathematics as one of "discovery and verification of ideas." Kay's views about mathematics and teaching were said to be consistent with Thompson's observations:

She frequently encouraged the students, in a rather persuasive tone, to guess, conjecture, and reason on their own, explaining to them the importance of these processes in the acquisition of mathematical knowledge. (p. 289)

Inconsistencies between beliefs and instructional practice have also been documented. Thompson (1984) described Lynn who believed mathematics instruction should encourage students to ask questions and participate actively in class discussions. Thompson observed, however, that Lynn's practice consisted primarily of lectures followed by routinized seatwork. These practices, which severely restricted student participation, interaction, and the opportunity to ask questions, were deemed inconsistent with Lynn's beliefs. Cohen (1990) provided a similar case analysis of a teacher named Ms. Oublier. Ms. Oublier believed she was implementing reform mathematics practices such as cooperative learning. Cohen, however, claimed that she had in fact maintained very traditional teaching practices that did not reflect the sense-making envisioned by the authors of the reforms.

There are many possible explanations for these perceived inconsistencies. It is certainly plausible for teachers to state beliefs and behave in a manner inconsistent with those beliefs. There are, however, other potential explanations tied to the methods and research designs used in this work that warrant consideration. In the following section, I provide a brief survey of methods typically used in this work to help explain how this interpretation may be an artifact of the methods used.

### **Typical Methods and Research Designs**

#### **Beliefs: Questionnaires, Interviews, and Observations**

Much of the work on beliefs is based on self-reports from teachers. Through questionnaires and/or interviews, researchers build descriptions of beliefs expressed by teachers. The methods employed range from large-scale surveys to in-depth case studies. From this research, a great deal is known about the beliefs teachers typically state. Beliefs are often categorized based on schemes such as the ones described above. These categorization schemes are sometimes derived empirically from the data and other times predefined categorization schemes are used in the collection and analysis of the verbal data.

In some instances, beliefs teachers state are augmented with ones inferred from observations. Some researchers contend that for an accurate portrayal of beliefs, "investigations of teachers' mathematical beliefs should examine teachers' verbal data along with observational data of their instructional practice or mathematical behavior, it will not suffice to rely solely on verbal data" (Thompson, 1992, p. 135). Typically,

researchers match their characterization of particular beliefs (e.g., mastery of skills is important) to behaviors observed that the researcher would consider consistent with holding that belief (e.g., devoting considerable class time to drill work on those skills). The methods used to attribute beliefs to teachers from observational data are not usually specified in much detail. In addition, rarely are definitions of descriptive terms presented—it is assumed that the teachers, researcher, *and the reader* understand the terms to mean the same things. Consider for a moment what saying “I believe group work is important” means to you. Would everyone share that meaning?

### **Practices: Observations and Teacher Self-Reports**

Data on teaching practices typically come from two sources: observations and teacher self-reports. Classroom observations are sometimes documented on video or audiotape. Fieldnotes or more structured systems for recording observations are common among written data-gathering methods. In most cases, these studies provide little detail about the methods used to analyze the observational data, and descriptions are often portrayed as if they have universally agreed upon definitions.

In some cases, data about instructional practices come not from observations but instead from teacher self-reports in interviews or on questionnaires. In these instances, teachers are asked to describe what their classes are like or queried about their use of specific teaching practices. Again, specifics about the methods and definitions are not usually provided. What does “The teacher led a discussion about problem solving” mean to you? What might it mean to others?

### **Connecting Beliefs and Practices**

Using data collected in the manner described above, some researchers examine the relationship between teachers’ beliefs and their in-class teaching practices. Typically, researchers look for correlations among beliefs and observed or reported practices. As with some of the methods described above, how these analyses are conducted is often described only in very general terms.

### **Professed and Attributed Beliefs and *Shared Understanding***

As noted earlier, researchers have found both consistencies and inconsistencies between beliefs and practices. This has led to separate classifications of what teachers say (professed beliefs) and what is reflected in their practice or inferred from other data (attributed beliefs) (Calderhead, 1996; Thompson, 1984). These classifications have influenced the research designs and methods used in studies of teachers’ beliefs and practices.

On the surface, using both professed and attributed beliefs seems like a very sensible way to ensure data are more representative of teachers’ beliefs. It is reasonable to presume that one needs information in addition to what is stated on a questionnaire or in an interview to fully understand teachers’ beliefs and practices, especially when teachers’ actions appear to contradict what teachers claim to believe.

As noted above, primary sources for information about teachers' beliefs include questionnaires and interviews. On a questionnaire or in an interview, terms used by the researcher to describe beliefs and practices (for example, "problem solving," "cooperative learning," "sense-making," etc.) may not carry the same meaning for the teacher as they do for the researcher. When a teacher says she believes she should foster "sense-making" of mathematical ideas in her classroom, can researchers be certain they know what the teacher means? When researchers ask teachers what they believe the role of problem-solving should be in their classes, how certain can they be that they and the teachers have similar understandings of what problem solving is? These disconnects mean that the resulting data may not accurately represent the teacher's beliefs or practices. I refer to this potential disconnect as a lack of *shared understanding* between the participants and researcher about the meaning of terms used.

This issue of shared understanding is also problematic when researchers make attributions of belief based on observations of practice. A typical example begins when a teacher states a belief (for example, "Problem solving is important"). Next, the researcher observes a class where the teacher has students work a series of procedural exercises—a practice the researcher does not see as reflecting a belief in the importance of problem solving. The researcher concludes that there is an inconsistency between what the teacher claims to believe and what she must really believe. The problem lies again in the presumed shared understanding. What the teacher did in the class may fit *her* conception of problem solving, and the teacher and the researcher may merely hold very different definitions. Saying her teaching does not reflect the *researcher's* conception of problem solving is not the same as saying that her beliefs and practices are inconsistent. (An example of this phenomenon can be found in Cooney's 1985 study of "Fred.") Unfortunately, the methods typically used to study beliefs and practices usually do not make it possible to formulate such a distinction.

I contend that the distinction between professed and attributed beliefs is a false dichotomy and an example of a particular consequence of the lack of shared understanding discussed above. It is quite plausible that there are situations in which teachers state one belief and behave in ways that are inconsistent with that belief. There are likely to be instances where teachers make statements that are (intentionally or unintentionally) inconsistent with what they carry out in their classrooms. I think, however, that it is possible that perceived discrepancies are sometimes the result of incomplete or inaccurate understanding of the terms and descriptions used by teachers and researchers. The apparent dichotomy may be a consequence of the methods used to study beliefs and not a true reflection of the nature of teachers' beliefs.

I also contend that it is inappropriate to classify any belief as "professed." When a teacher makes a statement of belief, the researcher shapes the way the data are portrayed. Even in cases for which transcript or other teacher-generated statements are used as data, the researcher has framed the presentation of the excerpt and provided

surrounding prose that color how the teacher's belief is portrayed to an audience. In these ways, all beliefs reported are to some extent attributed to the teacher by the researcher. Instead of designing methods that just access both attributed and professed beliefs, it seems more productive to devise methods that allow for the most accurate attributions possible.

### **Description of Novel Methods**

#### **Videoclip Interviews**

Work on beliefs is highly dependent on the descriptions and terms used by researchers and teachers. To improve the accuracy of the attributions of belief I wanted to increase the chances that teachers and I had shared understanding of terms used to describe beliefs and practices. To build shared understanding, videotape data of classroom practices was collected and used as the context for "video clip" interview discussions. For a more extensive description and discussion of these methods see Speer (2001).

The video clip interview technique was based in part on other researchers' use of "videoclubs" as a professional development activity and as a source of data on teacher cognition (Frederiksen, Sipusic, Gamoran, & Wolfe, 1992; Nathan, Knuth, & Elliot, 1998; Sherin, 1996). The teacher's class was videotaped on multiple occasions. After each class, I viewed the tape and selected clips for discussion. During each interview, I played clips and asked the teacher to explain what he or she was doing and why.

By using video clips of the teacher's class in the interviews, I hoped to obtain information beyond what is possible to obtain in traditional, de-contextualized interviews or in a combination of interviews and observations. As discussed below, I believe the use of video clips can help build shared understanding by allowing vocabulary to emerge and by providing a meaningful context for the discussions.

Emergent definitions and vocabulary. In a traditional interview, a researcher might ask, "What role does problem solving play in your teaching?" Terms such as "problem solving" do not have precise, universally agreed upon definitions. Researchers cannot assume teachers (or other researchers or readers) share definitions. I wanted the descriptive vocabulary and definitions used in the interviews to emerge in the context of the conversations and be inductively derived from the discussions.

If video clip interviews are used, a teacher can describe what was going on in the classroom in his or her own terms. Instead of introducing words into the discussion with potentially ambiguous meanings, the words come from teachers. This comes with the obvious caveat that the researcher must seek to understand what the teachers mean by the words they use—a task made easier with the use of actual examples of classroom practices as discussed below.

Shared artifacts and increased connections to practice. Video clip interviews improve shared understanding by utilizing a shared artifact that grounds the conversa-

tion in examples of the teacher's practice. Instead of discussing beliefs and teaching practices in the abstract, a video clip provides a concrete context around which the discussion can be focused.

In a de-contextualized interview, the researcher might ask about questioning practices. Interpreting the teacher's responses in this situation might be challenging because of the multiple layers of inference needed. For example, the teacher had to interpret what the researcher meant by questioning practices and then the researcher had to interpret the teacher's response to the questions. A more complete understanding of what teachers and researchers mean when using particular words is possible if those words are tied to actual examples of practice. Although there is certainly still inference necessary in a video clip interview, the video clip provides a concrete example to build questions around and to make reference to in the discussion. The researcher can then match terms as understood by the teacher to illustrative examples and create a more accurate and complete understanding of what he or she means when using particular terms.

### **Data Example**

In this section I illustrate my claims about professed and attributed beliefs and the importance of shared understanding with a data example. The teacher was Karl, a doctoral student in mathematics. He was teaching a discussion section in a second semester university calculus course where substantial class time was devoted to collaborative group work. I first describe Karl's beliefs and practices as they might be reported using traditional methods. Viewed in this manner, there were inconsistencies between what Karl professed to believe and the beliefs that might be attributed to him based on observations. From video clip interview data, however, it was possible to develop a more thorough profile of Karl's beliefs and the apparent inconsistencies were resolved. I focus here on illustrating my claims and only discuss a few of Karl's beliefs. This example is drawn from a larger study of teachers' beliefs and practices (Speer, 2001).

### **Traditional Methods**

Analysis of interview data revealed that Karl believed he should promote "independence" in his students. He believed it was important that students learn to solve problems in their groups without relying on extensive assistance from him. He said, "there's some sense of independence you're trying to get them, I'm trying to get them." He said this was "because they're not always going to be in a nice, structured class where there's somebody who knows more than them. I mean at some point they're going to be in a situation where nobody can tell them what the answer is, nobody can tell them what the reason is."

In support of "independence" Karl believed students should figure things out for themselves and that his primary mode of interaction with them should be to ask ques-

tions to help them solve problems on their own. Karl described his role in class as, "Socratic. I mean, it's, it's, they know that I have the answers. It's like everybody, you know, I've got the answers for it, I'm not going to tell them. But I'm going to try to ask them and see if I can get them to figure it out by asking the right questions." Karl also believed mathematics was about ideas and relationships and felt that in addition to developing skills, students needed to understand mathematical concepts.

Inferences from observations, however, might lead one to conclude that there were inconsistencies between Karl's professed and attributed beliefs. Karl's manner of interacting with students did not reflect the idea of independence in the ways one might have expected. He did have students work on problems, but he did not provide very substantial scaffolding or problem solving support. His professed beliefs would lead one to expect a questioning style that drew out student ideas and helped them build on their existing understanding of the material. Yet, although he did ask many questions, he did not probe for student understanding or illuminate the mathematical ideas and relationships he professed to value. For example, he frequently asked very general questions such as, "What does the problem ask?" and "What should you do next?" When students were unable to answer, he neither asked more specific questions to bring out what the students did not know nor directed them to relevant features of the problem. His use of questions rarely helped students make progress and were not what most would call "Socratic."

### **Videoclip-based Methods**

Videoclip interviews revealed what Karl meant by terms he used and the perceived inconsistencies between his professed and attributed beliefs were resolved. The shared artifact of videoclips of Karl's actual practice permitted me to develop a richer understanding of Karl's descriptions of both his beliefs and teaching practices. To Karl, asking the kinds of questions he asked and interacting with students in the manner he did were both consistent with his beliefs about promoting independence.

Karl believed that to promote independence, students needed to learn to ask themselves a set of "stock" questions. He believed the main obstacle preventing students from solving problems was their failure to ask themselves these questions. He said that "often when I asked them these questions, I try to ask the same questions enough times that they start getting it in their heads that these are good questions to ask themselves." He went on to say, "I try to always have kind of a stock set of questions so that after awhile they start hearing the questions in their own head." He said that the questions were the main thing that would help students learn to be independent and he added, "Especially, especially the more general questions." Although as an outside observer, one might not infer Karl's belief in "independence" from his use of questions, Karl believed he was helping students learn to be self-reliant and solve problems on their own. To Karl, the general questions he used were completely aligned with his conception of "Socratic."

From these and other discussions with Karl, I came to understand what he meant by the terms he used. Not only did “promoting independence” have a different sense than one might have expected, but so did his concept of “Socratic questions,” and other descriptive terms he used. Once I had this understanding, there was no longer any inconsistency between his professed beliefs and what I would attribute to him from observing him teach.

### Conclusions and Implications

Why is it that researchers have found a dichotomy between professed and attributed beliefs? Current theory does not explain *why* consistencies or inconsistencies might exist. I think the answer may be in part because the methods used have influenced the data that have been collected. I contend that some differences may be in part due to a methodological artifact. In particular, the dichotomy may arise when researchers and teachers lack a shared understanding of the words and terms used to describe beliefs and practices.

When researchers discuss “professed” beliefs, most often they are referring to words teachers have said. Although data may be actual statements made by teachers, researchers introduce layers of interpretation simply by selecting particular data and conducting analyses. In addition, the discussion and descriptions are not linked to specific referents. Therefore, although beliefs may be classified as professed because the data source is statements made by the teacher, in reality, the researcher has made attributions. Using videoclip interviews to illicit teachers’ thinking and reasoning about their teaching practices provides access to information that it not possible to obtain using typical interviews and/or observations. The methods I used provide one way of building shared understanding and generating more accurate attributions of beliefs.

Whether researchers use videoclip interviews or other methods for obtaining data on teacher’s beliefs, it seems likely that substantial progress in this area of research will occur if we concentrate on developing and using methods that will enable the most accurate attribution of beliefs possible instead of focusing on distinctions between professed and attributed beliefs. As attention to beliefs becomes an increasingly common component of teacher preparation and professional development programs, it is important that the research community strives to ensure that representations of teacher’s beliefs are as accurate as possible.

## **BELIEFS ABOUT STUDENTS' MATHEMATICAL ABILITIES: HURDLE OR SPRINGBOARD TO GRAPHING CALCULATOR USE?**

Teresa G. Banker  
Kennesaw State University  
thebankers@mindspring.com

The research study, on which this paper is based, focused on preservice teachers' beliefs and practice regarding the use of graphing calculators in mathematics instruction. In particular, the study looked at how the graphing calculator was used and with what mathematics the calculator was used. The paper describes the teachers' beliefs about student learning and beliefs about students' mathematical abilities because the study showed that teachers' beliefs about students' mathematical abilities influenced how the graphing calculator was used and influenced the range of mathematics taught in the classroom.

This report is based on a 15-week study of two secondary mathematics preservice teachers, and it describes their belief systems about students' mathematical abilities in terms of Green's metaphor (1971). The teachers' belief systems are consistent with the structure proposed by Green, and the uses of the graphing calculator by these teachers during student teaching paralleled the uses found by Simmt (1997).

### **Perspectives or Theoretical Framework**

Green (1971) developed a thorough description of the structure and properties of belief systems. This description posits how beliefs are held rather than what those beliefs are. He explained that belief structures have three aspects of which they are comprised: the relationship between beliefs, the strength with which they are held, and the cluster effect of beliefs. The organization of a person's beliefs is a logical order consisting of primary beliefs and derivative beliefs. Primary beliefs are those beliefs that are very basic to a person's actions; usually the person cannot justify this belief because it is self-evident to her. Derivative beliefs are those beliefs that develop logically out of other beliefs.

Psychological strength is another descriptive term about how beliefs are held. Beliefs that are held passionately are called core beliefs and live at the very center of the person's belief structure. These beliefs are the person's foundation, and, thus, are very difficult to change. On the other hand, beliefs that are held with less strength are called peripheral beliefs and can be more easily changed.

A person's belief structure contains isolated clusters of beliefs, and within these clusters, the beliefs are consistent. However, from cluster to cluster, the beliefs may be inconsistent. Such inconsistencies may cause turmoil only when the clusters are compared side-by-side; thus, a person can hold inconsistent beliefs as long as the beliefs remain in isolated clusters.

Evidence for holding beliefs is another important aspect that Green described. Some beliefs are held evidentially and some are held non-evidentially. Beliefs that are held evidentially are open to challenge because the reasons for the belief may be disputed by other evidence. Non-evidential beliefs are highly resistant to change because they are held without evidence or reason.

Simmt (1997) provided categories of use for the graphing calculator that described how inservice teachers used the tool when teaching quadratic transformations. Those categories of use were as a tool for 1) checking work, 2) plotting graphs of functions, 3) finding graphical solutions, 4) understanding word problems, 5) exploring beyond the concept being taught, and 6) providing a picture. Green's description of core beliefs best relates to the preservice secondary mathematics teachers' beliefs about students' mathematical abilities and how those beliefs influenced the teachers' uses of the graphing calculator.

### **Methods and Data Sources**

Two preservice teachers, Fiona and Hope, were observed and interviewed about graphing calculator use during student teaching. The observations and resultant interviews occurred both at the beginning and the end of student teaching to provide a comparison of how the graphing calculator was used in instruction. Preliminary essays and surveys with an interview were used to determine existing beliefs about mathematics and mathematics education at the beginning of student teaching, and two essays were written after the conclusion of student teaching. The constant comparative method of data analysis (Creswell, 1998; Merriam, 1998) was used to shape subsequent instruments for data collection.

The data for this study were collected during student teaching and the seminar for teaching mathematics that follows student teaching. The data consist of preliminary essays, surveys (one essay and two surveys), and one individual interview during the first week of student teaching; two individual interviews, five classroom observations, and three e-mail prompts-responses during the remaining weeks, and two final essays written during the seminar—all for each preservice teacher.

### **Results and Conclusions**

During student teaching, both preservice teachers worked in situations that involved skill-challenged mathematics students in classes of pre-algebra and applied algebra. The researcher examined with what mathematics content the graphing calculator was used and found two content areas: computation and algebra. Within each of these areas were several arenas of that content. Thus, the researcher labeled five arenas for computation (i.e., arithmetic operations, statistical, probabilistic, evaluative, and trigonometric) and six arenas for algebra (i.e., solving one-and-two-step equations and inequalities, lines—including linear regression problems, and creating T-tables).

Fiona's students had low arithmetic skills, evidenced by previous failure in the class she was teaching and in the skills assessments she did during the first week of student teaching. She saw this evidence as an indication of what was possible in her classroom. In most, if not all, of the classroom observations for Fiona, the researcher noted Fiona's statement that students could get correct answers if they knew how to use the graphing calculator. Her core belief was that students' low arithmetic skills limit graphing calculator use to verifying answers. As a result of this belief, she planned her lessons around the use of verifying answers, the lowest level of graphing calculator use. More evidence to support this core belief presents itself for Fiona's class in the limited content arenas. For computation, only two arenas were evident: arithmetic operations and evaluative. For algebra, the only arenas evident were solving one-and-two-step equations and inequalities and creating T-tables for lines. Fiona confirmed the researcher's conclusions with this statement: "I was wrong. I thought their low arithmetic skills meant they could only verify answers, but they were using the calculator to generate alternate solutions and to explore other concepts. Next time I'll know what to do."

Hope's students also had low arithmetic skills, evidenced by the level of the mathematics curriculum in which they were enrolled. However, Hope's core belief stemmed from her confidence that all students could do many levels of mathematics given appropriate tools. Hope believed that the graphing calculator was an appropriate tool to help students do all levels of mathematics, and she used the graphing calculator accordingly. She said, "Look at the linear regression. This would not even be available to my students without the calculators. If I tried to teach them how to do linear regression, I'd lose them, and they wouldn't see the line. The calculator is amazing!" Hope's core belief about her students' mathematical abilities and graphing calculator use opened a broader range of mathematics. For Hope's students, it appears that the teaching of much deeper and richer mathematics was possible. Evidence for this conclusion also comes from the content arenas used in Hope's teaching: computation content involved the arenas of arithmetic operations, statistical, probabilistic, evaluative, and trigonometric; algebra content involved the arenas of solving one-and-two-step equations and inequalities, lines—including linear regression problems, and creating T-tables.

The study showed that teachers' beliefs about students' mathematical abilities do influence graphing calculator use. For Fiona, her belief that low arithmetic skills implied verifying answers with the calculator was a hurdle for graphing calculator use. The limited content arenas in both computation and algebra suggested this problem, also. For Hope, her belief in the students' ability to learn many levels of mathematics given an appropriate tool, represented by the calculator, served as a springboard for graphing calculator use that provided opportunities for teaching deeper and richer mathematics in her classroom.

## **EXAMINING THE ROLE TEACHERS' BELIEFS ABOUT MATHEMATICS AND EXPECTATIONS OF STUDENTS PLAY IN SELECTING AND IMPLEMENTING CURRICULA**

Lecretia A. Buckley  
University of Illinois at Urbana-Champaign  
lawilson@uiuc.edu

Low achievement and failure in mathematics classes are far too familiar experiences for too many students. Consequently, mathematics teachers and mathematics departments are challenged to respond to these experiences in ways that enhance learning and facilitate success. This research study examines two high school mathematics teachers' efforts to address student failure. The teachers collaborate to design and "co-teach" a mathematics class for students who had failed the first semester of their mathematics class. I refer to this newly formed class as Math Skills. The teachers selected a skills-based curriculum in an attempt to construct a mathematics class that enabled students to acquire or fortify their proficiency in pre-algebra and algebra topics. The teachers' beliefs about the nature of mathematics were integral to the selection of the curriculum and to the goals and standards the teachers set for the course and student performance. The research questions that guided my inquiry were: (1) What are the teachers' beliefs regarding the nature of mathematics? (2) What are the relationships among the teachers' beliefs about the nature of mathematics, their beliefs about students' enrolled in Math Skills capacity to do mathematics, and their goals for the class and the students in the class? and (3) What are the results of the implementation of the curriculum, especially as it relates to the impact this implementation had on the teachers' aforementioned beliefs.

This research was conducted in a mathematics class that was taught in a high school with an enrollment of approximately 1500 students. The school, Prairie High School (a pseudonym), is located in a small, Midwestern city. The mathematics department and the district's Board of Education authorized the addition of the class in order to provide a mathematics learning experience to students who had failed the first semester of their mathematics class and who would otherwise be placed in a non-mathematics course for the second semester. Two primary goals of the course were: (1) the students would learn mathematics skills that would promote their success when they reentered the mathematics class that they had previously failed and (2) the class would present an opportunity for continuous mathematics learning which would not have been afforded if they were placed in a study hall or other content area classes.

This research considers the teachers' efforts and how their views about mathematics and their expectations of their students influenced those efforts and vice versa. Research supports the claim that teachers' views of mathematics influence instruction and curricular-related decisions (Dossey, 1992). Moreover, different views of the

nature of mathematics (e.g. a body of absolute truths or fallibilist) promote varied foci during the selection of curricula and instruction (Lerman 1998). Stodolsky & Grossman (2000) argued that teachers' perspectives on the nature of mathematics influence their views on what content to teach. Thus teachers' views on the nature of mathematics are significant when considering the selected curriculum and the methods of instruction utilized in the implementation of that curriculum.

Additionally, teachers' beliefs and expectations about their students are significant. Research suggests that students perform at higher levels when teachers hold high expectations of them (Gutierrez, 1996; Silver & Stein, 1996). Talbert, McLaughlin, & Rowan (1993) asserted that teachers' decisions about what should be taught were influenced by their expectations of their students. Therefore, the examination of teachers' expectations of their students can shed light on both the selection of particular content to teach and the methods of instruction in which the teachers would engage in the implementation of selected curriculum.

I collected data in the form of field notes from weekly classroom observations, audio-taped, semi-structured interviews with the teachers, and journaling. Collaborating with a research team that consisted of one professor of mathematics education and two other graduate students, I developed a coding system to analyze the transcripts of the interviews and field notes. Our inquiry was framed by research on teachers' beliefs and how those beliefs are challenged (Cooney, Shealy, & Arvold, 1998; Green, 1971). Predetermined codes on the nature of mathematics (procedural, static, dynamic, sequential, or well-defined) and teachers' expectations of students (high, low, and/or related to innate ability) were defined and later revised throughout analysis. Codes regarding how mathematics is learned included drill and practice, sense making, applications, and rote/memorization. I triangulated across data sources and participated in weekly research team meetings in which data were presented and analyzed and alternative analytic perspectives of inferences were examined. Prevalent themes that I identified through the implementation of constant comparison analysis (Strauss, 1987) guided the focus of subsequent observations and interviews. Emergent themes included a procedural view of mathematics, low student expectations, and skill-acquisition as the goal for mathematics learning.

This study reaffirms connections between teachers' beliefs about the nature of mathematics and how mathematics is learned and the curriculum they implemented. The teachers held a procedural view of mathematics and believed that drill and practice would achieve mathematics learning for students in Math Skills. The selection and implementation of the curriculum were influenced by the teachers' low expectations for the students. While the aforementioned findings are not surprising, the students' poor performance in Math Skills appeared to have opened a door for the teachers' reconsideration of how mathematics is learned and the efficacy of a low-level, skills-based curriculum in meeting their students' needs. Both teachers' stated that assessing the success of the course would be partially dependent on the students' performance

when they reentered the previously failed class. However, they both suggested that the drill and practice approach had not been successful for promoting engaged learning or skill retention as they previously thought. One of the teachers taught a similar class the following year and incorporated field trips, projects, and connections with college mathematics students in an effort to promote more engagement and learning. However, a focus on drill and practice remained. Yet, teaching Math Skills provided the teachers with firsthand evidence that brought the efficacy of a low-level, skills-based curriculum in meeting the needs of previously unsuccessful students into question. Findings suggest that efforts to enhance mathematics instruction that allow opportunities for teachers to engage in the practices they believe will work coupled with critical discussions and reflective interchanges on students' performance can promote a reconsideration of beliefs about how mathematics is learned.

## **MATHEMATICS TEACHERS' PERCEPTIONS OF COMPUTERS USE IN MATHEMATICS INSTRUCTION: A CASE STUDY FROM TURKEY**

Erdinc Cakiroglu  
Middle East Technical University  
erdinc@metu.edu.tr

Cigdem Haser  
Middle East Technical University  
chaser@metu.edu.tr

The purpose of this study was to explore Turkish middle school mathematics teachers' perceptions of a mathematics learning environment when computers were used for drill and practice purposes. Data for this study were collected through interviews. The results of the study were presented with a focus on the perceptions of the roles of teachers and students, environment, instruction and interaction when computers were used.

### **Introduction**

Research has shown that a vast majority of teachers in Turkey had positive beliefs about the use of computers in education, but had limited knowledge and experience on how to use this technology in their teaching (Cakiroglu, Cagiltay, Cakiroglu, & Cagiltay, 2001). A major obstacle for not using computers in teaching was the lack of hardware and lack of teachers' knowledge in computers (Cakiroglu et al., 2001). International experience on this issue suggests that, even if the computers are available and accessible, mathematics teachers tend to not use computers in their classrooms (Rosen & Weil, 1995). Especially, when mathematics teachers hold negative beliefs about the computer use in mathematics instruction, this may be a reason for not using the computers in their teaching (Norton, McRobbie, & Copper, 2000). In this sense, how mathematics teachers perceive the use of computers in the mathematics classrooms becomes an important issue for understanding the issue of integrating the computer technology in mathematics curriculum.

Research suggests that when used in mathematics classes, computers may have an important impact on classroom culture, which could result in different roles for both teachers and students (Fraser, Burkhardt, Coupland, Philips, Pimm, & Ridgway, 1987; Heid, Sheets, & Matras, 1990). A major concern of teachers in such a learning environment was related to classroom management (Jensen & Williams, 1992). Teachers' perceptions of computers in the mathematics classes seemed to be affected by various factors related to their background. Individual teachers' resistance to the use of computers in the class was found to be connected to their beliefs about mathematics teaching and learning and their existing pedagogies, including their perceptions about examinations, concerns about time constraints, and preferences for particular text resources. When teaching was considered as transmission of knowledge with a subject-centered approach, individual teachers had a restricted image of the potential of the computers in teaching and learning. However, when teaching was viewed as a social constructivist process with a more student-centered approach, an individual

teacher had a broader view of the potentials of the computers in mathematics teaching (Norton et al., 2000).

The purpose of this study was to explore five Turkish middle school mathematics teachers' perceptions of a mathematics learning environment when computers are used. There was a focus on the differences that may likely to appear in their regular mathematics lessons in terms of roles, environment, instruction and interaction when computers were used.

## **Method**

### **Setting**

The research site was a private middle school in one of the major cities of Turkey. The school had two computer laboratories, and no computers were available in the classrooms. Available software for mathematics instruction was determined by the collaborative work of the research and development department and the mathematics department of the school. One of the major criteria in the purchase of an instructional software was its consistency with the national curriculum (In Turkey, there is a strict centralized curriculum that schools are expected to follow). Available software for mathematics classes was mostly based on drill and practice, where students usually perform the mathematical skills covered in the regular lessons, or solve questions related to that week's topics.

### **Data Source**

Among nine mathematics teachers in the school, the ones who had conducted lessons in the computer laboratory were selected as participants in this study. In total, five mathematics teachers were selected as participants. These teachers were interviewed about their perceptions of the use of computers in teaching mathematics. Interviews were recorded on the basis of teachers' approval. They were transcribed and analyzed initially by content analysis and then by phenomenological analysis as described by Bogdan and Biklen (1998).

## **Results and Discussion**

Findings suggest that, among the participants, views of using computers in teaching mathematics seemed to be related to their interest in computers. For instance, one of the teachers, who was quite competent in computers and expressed the importance of computers in her daily life, was interested in mathematics education software. She provided clear ideas on the use of computers in the mathematics classes, and how the software should be designed and used. She also described how she would use computers in her lesson, if they were available in her classroom instead of computer laboratories. Another teacher who had limited experience in using computers was not very interested in the use of computers in mathematics instruction. She claimed the uselessness of the computers in the mathematics classes almost on any condition.

Teachers' expectations from their students had similarities in terms of the behaviors they expect to see in their classes. Respect was one of the most emphasized issues. In terms of mathematics instruction, teachers claimed that the students should contribute to their own learning. In this respect, doing homework on time was clearly emphasized by most of the participating teachers.

A common concern of the teachers during the mathematics lessons in the computer laboratories was related to the management of the classroom. They stated to have difficulty on keeping track of student progress, and maintaining the orderliness of the lesson. In this respect, teachers tended to believe that students loved dealing with computers during mathematics lessons conducted in the computer laboratory. As one of the teachers stated, to some extent, this may be due to the fact that students are "freer and more relaxed in computer sessions." She stated that in her regular mathematics lessons, she has the control of what is going on during the lesson. According to her, the case is quite different in computer sessions, where "students can sit anywhere they want and chat with classmates" which are "disorderly" and inconsistent with her regular mathematics classes. In this sense, she preferred to have the computers in her classroom, instead of computer laboratory. Unlike their regular mathematics lessons, she felt to have a more "passive" role in the computer laboratory sessions, which she did not prefer. She thought that students are more "serious" in her mathematics lessons without computers.

Although teachers appreciated that students enjoy mathematical work they do on computer sessions, they complained that they lost control of the flow of the lesson. Such concerns of teachers related to the classroom management were consistent with the arguments of Jensen and Williams (1992).

Willingness to use various instructional methods also seemed to be related to their perceptions of using computers in the classroom. Among the participating teachers, the ones who seemed to be open to changes, such as trying to use different teaching methods, were also open to the use of the computers.

A common belief among the teachers was that during the mathematics lessons in the computer laboratories, male students were mostly interested in computers just because they like to use them, while female students are interested more on the mathematical tasks presented by the computers. During these sessions, teachers believed that female students were more "careful and spend more time on the mathematical tasks" presented by the computer, compared to male students.

## **ONE & DONE: "VERY LITTLE PREPARATION FOR TEACHING WITH TECHNOLOGY"**

Michael D. Hardy with Floyd M. Spears  
Harding University  
mhardy@harding.edu

This paper highlights the results of an investigation of pre-service elementary teachers' perceptions of their ability to teach via technology and of how their degree program prepared them to so teach. Results indicated that participants tended to perceive themselves as capable of teaching via technology. However, they had difficulty identifying specific technological resources for teaching. Further, participants tended to be less positive in their perceptions of both the extent to which their degree program prepared them to teach via technology and the extent to which their instructors modeled the effective use of technology than in their perceptions of their own ability to teach via technology. Accordingly, modifications to teacher education programs may be warranted and some suggested alterations are provided.

### **Goals and Participants**

In the spring of 2000, I (M. H.) began an investigation of pre-service elementary teachers' perceptions of their preparedness to teach via technology and of how their degree program prepared or failed to prepare them to so use technology. The participants were 43 pre-service elementary teachers within 2 weeks of completing their undergraduate degrees. Cohorts of students took fixed blocks of courses during their senior year, which for most participants was a precursor to a fifth year of study and an internship leading to an MAT in Elementary Education. However, no participant had completed a student teaching experience.

Of the 43 participants, 27 were my (M. H.'s) pupils. Of these, 7 were enrolled in one integrated instructional methods course 20 in another. I taught methods of teaching mathematics to both sets of students, and a colleague taught the language arts components for both courses. An instructor I shall refer to as Mr. K taught the social studies and science components of the course in which 20 of my students were enrolled. Another instructor taught the corresponding components for the rest of my pupils, and the remaining 16 participants were students of three different educators.

### **Methods and Tentative Hypotheses**

Data was collected through a survey that contained both 5-point Likert scale and open-response items. Frequency counts, percentages and chi-square tests were used to identify patterns in Likert scale data and coding was used to identify patterns in the open-response items. As a check on the participants' assessment of their preparedness to teach via technology, I (M. H.) asked them to list 3 specific technological resources for teaching each of the disciplines of mathematics, science, language arts and social studies.

I began the study with the tentative hypothesis that the pre-service teachers would not perceive themselves as ready to teach via technology. I also suspected that the participants would tend to disagree with the statements that their teacher preparation program prepared them well for teaching via technology and that their instructors modeled the effective use of instructional technology (Topp, 1996).

### Results

The pre-service teachers generally perceived themselves as capable of teaching through technology (83% A or SA & 100% N to SA). When asked to list 5 technological resources with which they had become familiar through their education courses, participants cited resources such as the Internet, e-mail, Power Point, spreadsheets, software and videos. When asked to identify 3 specific technological resources for teaching each of the disciplines of mathematics, science, language arts and social studies, most participants again noted 2 or 3 broad categories of technological resources such as the Internet, videos and email. The Internet, software, videos and laser discs were noted on the questionnaire, so those and other broad responses were not considered specific tools. Only 8 of 43 or 18.6% were able to list at least one title. However, 16 more participants for a total of 24 or 55.8% of the participants provided a response that indicated some knowledge of specific technological resources or where to locate them.

We find these percentages disconcerting. It is possible that the participants simply had difficulty remembering titles, but the percentages could be indicative of insufficient knowledge of educational technology. Accordingly, it is possible that the participants' perceptions of their ability to teach via technological resources are unrealistic. Some support for the latter possibility is found in the fact that the participating teachers tended not to be as positive in their evaluation of the extent to which the university prepared them to use technology as an instructional tool (SA 7%, A 28%, N 37%, D 21%, SD 7%). Likewise, the participants tended not to agree as strongly when asked if their instructors had modeled the effective use of technology (SA 7%, A 39.5%, N 41.9%, D 11.6%) (Topp, 1996). Moreover, very intriguing patterns existed in the responses to the questions requiring participants to list 3 specific technological resources for each of 4 disciplines. As noted above, 24 participants gave responses indicating some knowledge of specific technological resources or sites at which such resources could be found. Eight of the 24 were able to identify at least one specific technological tool. However, 62.5% of those noting specific resources and 75% of those displaying some awareness of such resources were in Mr. K's class, which comprised only 46.5% of the participants.

In light of the above, we separated the participants into two groups, those in and those not in Mr. K's class and re-examined their ability to identify a specific technological resource. We found that 5 of Mr. K's 20 pupils were able to highlight a specific technological tool, while 3 of the remaining 23 participants were able to do likewise.

Further, 16 of Mr. K's 20 students displayed at least some awareness of specific technological resources, while only 8 of 23 remaining participants displayed such awareness. A  $\chi^2$  test for significant differences in frequencies revealed no statistically significant difference in the frequencies of identification of a specific technological tool across the two groups. However, a  $\chi^2$  test did reveal a significant difference ( $p = 0.003$ ) in the frequencies with which Mr. K's students and the rest of the participants displayed at least some knowledge of specific technological resources. Thus, there is a relationship between being a pupil of Mr. K and demonstrating awareness of specific technological resources. This does not mean that Mr. K. was the cause of the awareness, but it is certainly a possibility and an issue that warrants further investigation.

The previously noted lack of support for the claim that the participants' instructors modeled the effective use of instructional technology was also highlighted in 60% of the responses to an open-ended question concerning how the university had failed to prepare the participants to teach with technology. Moreover, 83.7% of the participants indicated that they did not receive enough instruction regarding methods of teaching through technological resources. Similarly, 44.2% of the pre-service teachers highlighted having only one course dealing with technological resources as a weakness of their degree program (Topp, 1996). Even so, 46.5% of the participants also noted that they were given assignments such as developing Power Point presentations, which would certainly contribute to the participants' preparation to use technology as an instructional tool. Additionally, 39.5% of the pre-service teachers noted that some instructors did incorporate technology in their teaching.

### **Implications and Potential Solutions**

Data indicates that educational technology courses are preparing pre-service teachers to download lesson plans, find useful websites and to create spreadsheets and Power Point presentations. However, the difficulty participants had in identifying specific technological resources and the pervading perception (83.7%) of a need for further instruction concerning such resources and methods of teaching through them, suggests that teacher educators (at least at the participating university) need to reconsider the nature and scope of teacher preparation programs. Additional support for this claim is found in the pre-service teachers' assertions that their instructors did not model the effective use of technology (39.5%) and that having only one course focusing on technology was a weakness of their degree program (44.2%).

However, due to the wide range of majors served by educational technology courses, it is impossible for one course to adequately prepare pre-service teachers to teach via technology. Even so, we assert that pre-service teachers should be exposed to some technological resources for teaching mathematics, science, language arts and social studies during their educational technology course(s). Likewise, such courses should address criteria for evaluating technological resources and some general guidelines for teaching with technology. Nevertheless, methods courses should also address

these issues. Further, pre-service teachers need to extensively explore technological resources and to experience the use of such resources from the perspectives of both learner and teacher (Benson, 1997; Roblyer & Erlanger, 1999).

We propose that one method of helping pre-service teachers to become familiar with technological resources is to have them review and critique such resources. Assignments of this nature afford the bonus of requiring pupils to consider guidelines for evaluating technological resources. Pre-service teachers should also use technology to resolve problems, practice skills and learn or apply concepts and procedures. Finally, pre-service instructors' knowledge of technology and methods of teaching through it could be broadened by planning and teaching lessons in which technology was used as an instructional tool.

## CHANGE IN URBAN TEACHERS' BELIEFS BETWEEN THE END OF STUDENT TEACHING AND THE END OF THEIR FIRST YEAR OF TEACHING

Lynn C. Hart  
Georgia State University  
ECELCH@langate.gsu.edu

### Rationale and Theoretical Perspective

The role of beliefs in teacher change is well documented. A substantial body of literature exists which suggests that teachers' beliefs drive their teaching of mathematics (Pajares, 1992; Richardson, 1996). In order to change teachers' practices, we need to consider teachers' beliefs. However, we know that beliefs are difficult to change (Lerman, 1997; Pajares, 1992), that the beliefs teachers' espouse are not always consistent with the way they teach (Cooney, 1985), and that changing teacher's beliefs takes time (Richardson, 1996). Moreover, Pajares (1992) tells us that beliefs about teaching are well established by the time a student enters college. They are developed during what Lortie (1975) calls *the apprenticeship of observation* that occurs over their years as a student. They include ideas about what it takes to be an effective teacher and are brought to their teacher preparation program. Given this, it seems imperative that teacher education programs assess their effectiveness, at least in part, on how well they nurture beliefs that are consistent with the program's philosophy of learning and teaching. Also, it is important to study how consistent the beliefs teachers espouse are with their teaching practices, i.e., can teachers do more than *talk the talk*.

### The Intervention

The Urban Alternative Preparation Program (UAPP) is housed in the Department of Early Childhood Education at a large, urban university. Students enter as a cohort taking all coursework together. They hold non-education undergraduate degrees and are preparing to become certified in a K-5 *urban* setting. The program is grounded in constructivist learning theory and promotes practices that support that perspective.

In Phase I of the program, students obtain certification after four semesters. Unique aspects of this teacher preparation program include coursework and field experiences in the urban classroom and an integrated four-course sequence in mathematics-related content: two in mathematics and two in mathematics education. One faculty member teaches the twelve semester hours of content and methods as an integrated, seamless course over three consecutive semesters. Instruction is consistent with a constructivist philosophy. Students learn the mathematics from the mathematics book using many of the methods suggested in the methods book. They use oral reflection, videotaping and written logs to examine the methods used to deliver the content. The same mathematics faculty member who delivers the content in their coursework mentors them in their field placements. (For a more complete description of Phase I see Hart 2002.)

To continue on into Phase II students must have accepted jobs teaching elementary school in an urban setting (defined for our purposes as schools with at least 75% free or reduced lunch). During this time students pursue a masters degree. Their mathematics coursework during Phase II includes a course that provides monthly coaching in mathematics (content and methods) in their individual classrooms and a university course on Issues in Teaching Mathematics in the Elementary School. In addition to delivering content, the course provides a mechanism for these novice teachers to collaborate and reflect on their practice. The faculty member who teaches the mathematics in Phase I provides the coursework and mentoring in Phase II. (For a more complete description of Phase II see Hart 2001.)

### The Study

This study reports on the first cohort of students who entered the UAPP in May, 1999. In particular, the results of an item analysis of the Mathematics Beliefs Instrument (MBI) used at the end of Phase I and at the end of Phase II of the project will be discussed.

Fourteen of the original cohort of 20 teachers completed Phase I and obtained certification. Eight teachers took a teaching position in an *urban* school and are part of this study. They ranged in age from 25 to 41. There were two African-American females, one Asian male and five Caucasian females. Two teachers were in a first grade classroom, five teachers were in second grade and one was in third grade.

Results from the study comparing beliefs before entering UAPP to beliefs at the end of Phase I suggested that teachers had in fact changed in a direction more consistent with reform practices (Hart 2002). However, that research was only the first step in assessing change in their beliefs. As first year teachers in Phase II, I had the opportunity to look at their practice and assess how consistent it was with Phase I. Results from that study (Hart 2001) found that teachers had generally maintained their reform perspective that their teaching behaviors were moderately consistent with their espoused beliefs, but that they were greatly influenced by the culture of the schools within which they worked.

In reporting this work at PME last year it was suggested that an item analysis of the responses from the comparison of Phase I and Phase II instruments might provide a richer picture of the nature of change for these teachers. This short oral presentation will report on those findings. Because of the small number of participants ( $n=8$ ), only descriptive statistics are used.

Of the 224 possible response changes in self-reported beliefs on the MBI (28 items  $\times$  8), 80.4% (180 items) remained unchanged, 8.9% (20 items) changed in a direction more consistent with reform philosophy, and 10.7% (24 items) changed in a negative direction away from reform philosophy.

In analyzing the items I ordered items by the total *amount* of change in either direction and reviewed the qualitative data sources for possible explanations for the

change. I will give one example here. Item #17 (*some people are good at mathematics and some aren't*) had the largest amount of change with 6 teachers varying from their original response. Five teachers moved away from a reform perspective, accounting for 29% of the total amount of change on the survey. One teacher shifted toward reform. After analyzing the logs possible explanations emerged.

- All five teachers who had changed away from reform had, as first-year teachers, been given classrooms with the lowest performing students at their grade level; perhaps skewing their perceptions.
- Results from the MBIs indicated these teachers had changed their beliefs about what it means to be good at mathematics. However, the teachers were all in a culture of traditional mathematics practice. Being *good* at mathematics may have meant something different.
- The teachers reported that their students resisted engaging in conversations about mathematics and in sharing their thinking. One teacher commented that the students “just want me to tell them the answer.” The students did not fit the teachers’ new definition of being good at mathematics.
- In one class racial issues may have played a role in the teacher’s perceptions of her students and the students willingness to demonstrate their real ability. A white female teacher reported that “[one child] would tell me that she didn’t care what I said and that she wasn’t going to do the work because she hated white people.” This unwillingness to perform may have been perceived by some as lack of ability.

### Discussion

What have we learned from these results? For the most part, at this point in their professional development, these teachers appear to have generally maintained beliefs that are consistent with reform practices. However, a few teachers on a few items demonstrated some interesting change. Using the example of item #17, there appear to be many possible explanations for the teachers given the situation these teachers were working in, it is not unreasonable that after teaching for a year in a low-income setting with a traditional view of mathematics that they would believe that not all students are good at mathematics. From a programmatic point of view that information can inform our work with teachers during their pre-service experience so that we can do a better job of preparing them for the urban classroom.

## NAVIGATING THE WORLDS OF CONCEPTUALLY-ORIENTED MATHEMATICS AND STANDARDIZED TEST PREPARATION

Valerie Klein  
University of Pennsylvania  
vklein@dolphin.upenn.edu

Janine T. Remillard  
University of Pennsylvania  
aniner@gse.upenn.edu

This paper examines how a third-grade teacher navigated the potentially conflicting aims of developing students' conceptual understanding and preparing them for standardized tests. We situate our analyses of the teacher's understanding of mathematics and of herself as a mathematics teacher within the broader context of the school within which she practices and the educational culture in the United States. Like many elementary teachers, Gina Tyro found herself struggling to overcome her own negative experiences as a mathematics student and develop practices with which she was unfamiliar (Ball, 1994). We argue that it was a combination of the teacher's beliefs and experiences surrounding mathematics that prompted her to embrace a conceptually-oriented curriculum. However, the same beliefs and experiences initially limited the connections she was able to draw between the curriculum and the test-preparation lessons. The pressures she faced to both prepare students to do well on standardized test while fostering deep mathematical understanding is typical of many teachers in urban schools. How teachers understand and respond to these often competing goals can provide insights into current classroom practices and can guide efforts to support teachers in this work.

### Theoretical Framework

Our analyses were informed by research that examines classroom practices—in particular the participation structures established in the classroom in relation to teachers' beliefs about mathematics, teaching, learning, and educational goals. Typical classroom practices reflect views that mathematics consists of rules and procedures to be memorized and practiced. Thus mathematical learning can be measured by the extent to which a student can use these procedures accurately and efficiently. These beliefs about mathematics and what it means to know, which permeate mainstream culture, are acquired, "through years of watching, listening and practicing" (Lampert, 1990, p. 32) and influence the ways in which a teacher sets up her classroom. Lampert argued that teachers must work to initiate alternative classroom norms which "build a *participation structure* that redefines the roles and responsibilities of both the teacher and students in relation to learning and knowing" (p. 32).

Establishing such norms, however, often involves working against one's own deeply rooted beliefs about mathematics teaching. Thompson, (1992) used the term *integratedness* of belief structures to refer to the extent to which one's "beliefs and views in a given domain form a coherent conceptual system, as opposed to each belief existing in isolation from others" (p. 122). Lack of integratedness becomes apparent

when teachers try to develop practices that go against their established classroom norms.

Teachers' beliefs are not the only factors at play in shaping classroom practice. Other local goals, meanings, and events can mediate the classroom practices, leading to further inconsistencies between stated teacher beliefs and classroom practices (Thompson, 1992). In other words, knowledge and practices are contextualized socially and historically (Engeström, 1999), making change in practices considerably more complex than many might perceive.

### Methods & Data Sources

Our analyses involved a year-long ethnographic study of Gina, a third-grade teacher in an urban elementary school. Six teachers at the school had been involved in a project that combined professional support and research for two years. During that time, they used the reform-oriented curriculum, *Investigations in Numbers, Data, and Space* (TERC, 1998). Gina, a third year teacher in her first year at the school, used *Investigations* for the first time.

The data consisted of classroom observations, semi-structured interviews with the teacher, and informal conversations and classroom observations. We used QSR NVIVO to code and analyze the data. The initial coding was based upon a set of analytical questions about the observations, but emergent codes were also added.

### Results & Conclusions

Gina's recollections of her mathematics instruction were primarily negative and notably different from the practices she experimented with when using the *Investigations* curriculum. Her willingness to use the curriculum was impelled by her desire to offer her students a mathematics experience that differed from her own. From September to January, Gina drew upon the curriculum to encourage mathematical thinking, understanding, and the generation of computational strategies and explanations. Gina's confidence in and assessment of the curriculum were bolstered by her students' successful participation in these activities.

Even though they used the *Investigations* curriculum, many teachers at the school questioned the extent to which it prepared students to perform as expected on standardized tests, specifically the SAT-9. Thus, in consultation with a veteran third-grade teacher, Gina decided to devote two 2-week sessions to test preparation; she taught one in January and one in April. Her goal was to familiarize students with what she believed they need to know: the mechanics and rules of test taking and standard algorithms for multi-digit computation.

In January, she treated the test-preparation sessions as disconnected from her previous lessons. This shift was evident in the expectations she held for students and the norms she established in the classroom. She introduced the unit as follows: "This kind of math that I'm gonna show you today, it really doesn't involve a lot of thinking. And

that's why schools, decided to stop teaching it that way" (Observation 01/14/02). The students worked primarily on timed computation worksheets. Gina taught the students the conventional algorithms for addition, subtraction, and multiplication and expected the students to use those to solve the problems. The substantial change in participation structure observed during this instruction and the absence of any connections to their prior conceptual work was striking, particularly since much of the instruction we observed between September and January involved student-generated approaches to computing with 2- and 3- digit numbers.

Between January and April, Gina returned to the *Investigations* curriculum. In April, she began a second test-preparation unit. This time she made explicit references to work they had done from the *Investigations* curriculum. For example, she encouraged students to solve problems using whatever strategy they found to be quickest or easiest. While Gina encouraged students to connect these two approaches to learning math, she maintained that the two were incompatible and even irreconcilable. And she shared this view with her students: "SAT-9s use this weird math language we don't use. . . This is not math, this is SAT-9 practice" (Observation, 04/16/02).

The shift we found in Gina's inclination to encourage students to draw on unconventional computation strategies seems related to her observations of students using these strategies over time. In an interview in April, she explained with some surprise that many student-generated strategies were more efficient than conventional algorithms. In other words, Gina's teaching practices changed in response to changes she observed in students' mathematical practices. The interdependency of teachers' and students' practices illustrates the ways that classroom norms and practices are co-constructed and constantly shifting.

The pedagogical approaches Gina used in January suggest that at that time her beliefs about conceptual understanding and traditional algorithms were discrete as opposed to integrated (Thompson, 1992). Thompson (1992) (among others) argued for the importance of teacher reflection on the coherence between their beliefs and practices as a critical way for teachers to develop integrated systems. We are struck that Gina's reflection focused on the practices she and her students jointly constructed.

### Implications

The case of Gina Tyro raises several issues related to reform in mathematics education. First, Gina Tyro illustrates the possibility for students' mathematical practices to stimulate teacher learning. It is important to point out, however that the practices students developed were co-constructed by the teacher, the students, and the curriculum. Teacher learning and classroom practice do not follow a linear arrangement, but are intertwined and recursive. Teachers' beliefs are complex and deeply rooted and thus mediate practices and interpretations of new ideas. But they are also mediated by practice. Second, she illustrates the enormity of demands, sometimes conflicting, currently placed on teachers. As demands for accountability intensify, it is important

to understand how teachers navigated their associated conflicts. The field could benefit from more clarity on the relationship between computational mastery and conceptual learning. In recent years, the mathematics education community has been understandably driven by a pursuit of conceptual development. It is increasingly evident, however, that such emphases alone, can result in underserving many mathematics learners, particularly those in low-income communities. The field is in need of more studies of students' mastery of both computational and conceptual understanding in relation to different teaching practices (e.g., Boaler, 1997).

## **A CASE STUDY OF A NOVICE AND AN EXPERIENCED TEACHER IN THE IMPLEMENTATION OF A MULTIPLE REPRESENTATIONS CURRICULUM**

Nikita Danyelle Collins Patterson  
Georgia State University  
Nikita\_patterson@hotmail.com

The mathematics education community, in its call for reform, underscores the importance of mathematics instruction emphasizing the use of multiple representations in the presentation of concepts. One focus of the study was how teacher beliefs affect their ability to implement a multiple (algebraic, graphical, tabular) representations curriculum. The novice instructor's attitude remained neutral while the experienced instructor's attitude remained somewhat positive. The teachers had a great impact on the students' preferences for a particular representation and ease of technology use. Implications for further research were that teacher training is essential if reform curricula are to be properly implemented.

### **Introduction**

As mathematics educators explore ways to strengthen and energize their pedagogy, and as technology becomes more common in the classroom, the use of multiple representations is gaining more attention in the mathematics curriculum. The phrase *multiple representations*, in this study, refers to the presentation of a concept or process using numerical (table), graphical (Cartesian graph) and symbolic (equation) viewpoints (Noble, Nemirovsky, Wright, & Tierney, 2001; Porzio, 1999). Numerous researchers have investigated the effects of instruction using multiple representations of concepts (Dreyfus & Eisenberg, 1982; Harvey, 1991; Keller & Hirsch, 1998; LaLomia, Coovert, & Salas, 1988; Lloyd & Wilson, 1998; Noble et al., 2001; Porzio, 1999; Stein, Baxter, & Leinhardt, 1990). The conceptions teachers have about mathematical content can affect their ability to implement reform curricula (Fennema & Franke, 1992; Kidder, 1989; Lloyd & Wilson, 1998; Millsaps, 2000; Stein et al., 1990; Thompson, 1992; Wilson, 1994). The purpose of the study was to determine if and how teachers' beliefs about multiple representations and technology use will affect their implementation of the new curriculum. The research was guided by the following questions:

- 1) How will the teachers' beliefs about technology affect their ability to implement a multiple representations curriculum?
- 1) How will the teachers' beliefs about multiple representations affect their ability to implement a multiple representations curriculum?

### **Methodology**

The participants were instructors of two different sections of Intermediate Algebra at a large southeastern university. One instructor, "Joe", was identified as

the novice teacher and the other instructor, "Mary", was identified as the experienced teacher based on teaching experience, educational background and calculator proficiency. The teachers each selected four students from their respective classes to participate in the study. The students ranged in age from 17 to 19 and were selected to reflect diversity with respect to race, gender, and academic performance in class.

The data collection methods included interviews, classroom observations, audiotape recordings, videotape recordings, and artifact reviews. All interviews were videotaped and transcribed. All classroom observations were audiotaped and transcribed. Field notes taken during the observations focused on any teacher-student interactions that indicated the uses of multiple representations during classroom instruction. Written artifacts included the pretest, posttest, technology surveys, and observation sheets.

### **Results and Discussion**

Research shows that teaching with multiple representations leads to a better understanding of concepts (Hiebert & Carpenter, 1992; Kaput, 1989, 1992; Porzio, 1999). Contrary to the research, however, many educators are reluctant to embrace a multiple representations curriculum. Eisenberg and Dreyfus (Eisenberg & Dreyfus, 1991) have found that one of the reasons that teachers avoid visual explanations of mathematics is a sociological one; visual is harder to teach. The novice instructor, Joe, revealed in his interview that he was reluctant to teach the visual representations because he was not comfortable teaching them. He found it difficult to communicate to his students about mathematical relationships. He often missed the chance to promote meaningful connections between the concepts and the different representations. Joe also hesitated to use the calculator in class because he found it difficult to use during instruction. His hesitance was reflected in his teaching and affected his students' choices for representation use.

In contrast, Mary incorporated the graphing calculator into her instruction throughout the class period. She used each of the three representations almost equally (algebraic – 25.9%, graphical – 29.0 %, tabular – 16.1%, and a combination of the representations 29%). Similarly, her students also opted to use the various representations to solve problems and did not totally rely on the algebraic method. Mary's positive attitude, strong calculator proficiency, extensive teaching experience and beliefs played a crucial role in her implementation of the reform curriculum. Mary's conceptions contributed to a classroom environment in which she encouraged students to employ a variety of representations and make connections among them.

### **Conclusion**

It is not reasonable to expect Joe and Mary to approach the multiple representations curriculum in the same manner based on their dissimilar levels of experience and teaching styles. It is, however, reasonable to expect that Joe can effectively implement

this reform curriculum with the proper guidance and preparation. This training must include how to make connections between the various representations, and how to integrate technology into the classroom.

## **BELIEFS AND PRACTICES OF TEACHERS REGARDING FAILURE IN ALGEBRA**

Mary Pat Sjostrom  
Kennesaw State University  
msjostro@kennesaw.edu

This qualitative case study sought to understand the beliefs and practices of four Algebra I teachers who had high failure rates. The research used ethnographic techniques to examine teachers' beliefs about the nature of algebra, teachers' attributions for student failure, teaching efficacy as it related to student failure, and the ways in which teachers' attributions influence their practices. Strong connections were observed between the beliefs of the teachers regarding the nature of mathematics, their attributions for student failure in algebra, their self-efficacy, and the modifications they made in instructional practices. The study has implications for teachers, administrators, and teacher educators.

### **Introduction**

Currently there is a national trend to require algebra for all students. Yet historically many students have been unable to achieve this goal; the National Center for Educational Statistics reports a typical failure rate of 40-50% (Mullis, Dossey, Owen, & Phillips, 1991). The purpose of this research was to describe and understand the beliefs and practices of some Algebra I teachers who have high failure rates.

### **Theoretical Framework**

According to Pajares (1992), the broad construct of educational beliefs includes beliefs about the teacher's ability to affect student learning (teaching efficacy), about confidence in oneself to perform certain tasks (self-efficacy), about the nature of mathematics (ontology) and mathematical knowledge (epistemology), and about causes of teachers' or students' success or failure (attributions, locus of control, motivation). Beliefs play a critical role in selecting tasks and making decisions regarding such tasks, and therefore are instrumental in defining behavior (Pajares, 1992). A growing body of research provides evidence that teachers' beliefs about mathematics and mathematics teaching affect instructional practice (Brown & Baird, 1993; Thompson, 1992). Gibson and Dembo (1984) described several studies that found a positive correlation between teacher efficacy and student achievement.

### **Research Methodology**

The research project was a qualitative case study using ethnographic techniques. Participants were four teachers of beginning algebra at a metropolitan high school. Data were collected primarily through semi-structured interviews, supported by data from classroom observations and examination of artifacts. A teacher efficacy scale created by Gibson and Dembo (1984) was also administered. The researcher developed a

conceptual framework classifying factors in student failure as related to teacher (pedagogy, assessment, classroom management), student (ability, motivation, prerequisite skills), or system (curriculum, class size, resources). Attributions for failure were also classified according to whether they were in the teacher's locus of control. Data were analyzed to ascertain teachers' beliefs about mathematics and mathematics teaching, attributions for student failure, and the way these beliefs impacted teaching practices.

### **Findings**

All four teachers in the study had been taught reformed pedagogy and were familiar with the National Council of Teachers of Mathematics Standards (2000). However, they held an Instrumentalist view of the nature of mathematics, seeing it as a set of rules and procedures that must be mastered in order to advance to the next level of mathematics (Thompson, 1992). Their role was to demonstrate procedures, structure the classroom environment so that students could listen to explanations and practice the skills, and encourage students to work hard. Strong connections were observed between the beliefs of the teachers regarding the nature of mathematics and mathematics teaching, their attributions for student success and failure in algebra, their self-efficacy, and the modifications they made in instructional practices.

#### **Beth**

Beth (all names are pseudonyms) believed that the purpose of Algebra I was to prepare students for upper level courses, and was concerned about her accountability for their performance. Most of her attributions for student failure were related to student factors: their lack of motivation and self-discipline, and their inability to listen, understand and make connections, and retain knowledge. The locus was external to Beth and uncontrollable by her. These attributions had a strong influence on her self-efficacy and practice. Beth said she tried to explain things to students over and over again, "on the simplest level possible and use as many analogies as possible." She also talked about "making sure that they understand, making sure they do enough examples," though she acknowledged these strategies were generally ineffective. Beth had a lack of general and personal teaching efficacy, even stating at one point, "I'm just depressed about the future of mankind." She had trouble relating to students who found math difficult, and had difficulty with classroom management. By the end of the study Beth revealed that she was leaving education.

#### **Chad**

A strong proponent of the NCTM Standards, Chad believed that in Algebra I students should develop conceptual understanding to provide a good foundation for later mathematics. Unlike Beth, Chad stated that intellectual ability was a strong factor in determining success; students must be able to see patterns and organize schema efficiently. His judgment of students' achievement levels was based on a combination

of their cognitive ability, maturity and behavior, motivation and work ethic, and the influence of home environment. Although he attributed failure to many student-related factors, Chad believed that as a good teacher he could overcome most of these. He reflected on the pedagogy he employed, asking himself, "What is it I can do that... helps them to connect" concepts, and asserting that "the pedagogy really matters." This sense of control contributed to Chad's strong sense of efficacy.

### **Melissa**

Melissa focused on the negative aspects of the school's alternating day block schedule and large class sizes, both system factors out of her control. Another of her strong concerns was the fact that many of the students in Algebra I lacked the necessary prerequisite skills. Melissa attempted to take control by maintaining a highly structured classroom and, like Chad, she attributed much of her students' success to the teacher. Melissa modified instructional practices to accommodate her attributions for student success and failure, which in turn enhanced her teaching efficacy.

### **Ron**

Ron, the only one who did not hold a master's degree, was quick to point out that he was not a "math geek," asserting that his ability lay in explaining mathematics to at-risk students. Most of Ron's attributions for failure were student factors, particularly lack of ability and effort. Ron sometimes used projects to engage students and encourage them to put forth more effort, thus asserting his control and enhancing his efficacy. Ron had the highest failure rate of all informants (57%); however since these same students were failing many other classes, he determined that the failure was not attributable to him. As he told me, "I do my thing and I try to do it the best I can. And, you know, I think that in a lot of ways, see, I really care about the lower kids...And I can handle them."

## **Conclusions**

The teachers in this study believed mathematics is a set of facts, rules and skills to be learned and remembered, and the primary purpose of Algebra I is to teach students the skills and the organizational strategies needed for success in subsequent classes. Each teacher modified instructional practices in ways that were strongly linked to attributions for success or failure, to methods that enhanced personal teaching efficacy, and to strategies that had helped the teacher to learn.

This study has implications for teachers, educational administrators and policy-makers, and teacher educators. Teachers need to hold and communicate high expectations for all, building understanding through tasks that require higher order thinking skills. Administrators and policymakers must clearly define expectations for algebra, and provide teachers with the necessary curricula, training and resources. Teacher education programs must provide an opportunity for prospective teachers to learn content

from instructors who model Standards-based pedagogy, and lead them to reflect deeply on their experiences in order to effect a change in their beliefs and practices. Teacher educators also need to help teacher candidates develop new sources of efficacy based on their ability to help all students gain mathematical power.

# GEOMETRY

# THE ROLE OF A DYNAMIC SOFTWARE PROGRAM FOR GEOMETRY IN HIGH SCHOOL STUDENTS' UNDERSTANDINGS OF GEOMETRIC TRANSFORMATIONS

Karen Flanagan Hollebrands  
North Carolina State University  
Karen\_Hollebrands@ncsu.edu

This study investigated the nature of students' understandings of geometric transformations, which included translations, reflections, rotations, and dilations, as they used the technological tool, *The Geometer's Sketchpad*, within a high school Honors Geometry class. The researcher identified four purposes for which students used dragging and measures and analyzed the ways in which students applied their mathematical understandings to interpret and utilize technological results.

## Purposes

There has been a resounding call made by mathematics educators to incorporate the use of technology in high school mathematics classrooms (NCTM, 1989, 2000). In its most recent document, *Principles and Standards for School Mathematics*, NCTM 2000 states, "technology is essential in teaching and learning mathematics; it influences what is taught and enhances students' learning" (p. 24). Many believe the use of technology not only enhances students' learning but also provides students access to mathematical topics that were once reserved for college mathematics courses. One such topic is geometric transformations. The study of geometric transformations is an important topic to include in high school mathematics because it provides opportunities for students to think about important concepts (e.g., functions, symmetry), provides a context from which students can view mathematics as an interconnected discipline, and engages students in higher-level reasoning activities. The use of computer software, such as *The Geometer's Sketchpad* (GSP, version 3, Jackiw, 1991), offers students tools to explore geometrical relationships and may allow more opportunities for students to reflect on their activities. It is possible that the technology, because it makes visible students' actions and provides feedback that is based on geometrical relations and theorems, will facilitate students' development of deep understandings of geometric transformations. This study investigated the nature of students' understandings of geometric transformations, which included translations, reflections, rotations, and dilations, as they used the technological tool, *GSP* and were encouraged to create and explore conjectures and develop explanations. In particular, this paper addresses the following research question: In what ways does the technology support and constrain the understandings that high school students develop when learning geometric transformations with *GSP*?

### Perspectives

With such strong encouragement for using technology in mathematics classrooms, it is important to examine how the use of technological tools supports or constrains students' development of mathematical understandings. The role of such tools in shaping students' understandings is often described in terms of the affordances offered by and constraints imposed by tools. The affordances of the tool, as described Wertsch (1998), refer to how tools can enable and empower actions or thoughts. One can also examine the ways in which tools may constrain the actions that are allowed and the understandings that develop. In thinking about *GSP* as a tool, one can study the ways it may support students' thinking about geometrical objects, properties, and relations because of its dynamic nature; this type of reasoning might be more powerful than simply thinking statically about the material object present on paper or on the computer screen. The former type of reasoning might be thought of in terms of reasoning about the figure whereas the latter type of reasoning might be thought of in terms of reasoning about the drawing (Laborde, 1993). Several researchers have described how different modalities inherent in a dynamic geometry tool, such as dragging, may offer affordances and impose constraints on students' reasoning about drawing versus figure. For example, Arzarello et al (1998) described three different dragging modalities exhibited by students: 1) wandering dragging, 2) dragging test, and 3) lieu muet dragging. Wandering dragging refers to dragging in a somewhat random fashion. The student may not have a particular goal in mind for the dragging activity. Dragging test refers to dragging to check the construction to determine if the construction resists dragging. If a geometrical object has been constructed that its properties should remain invariant under the drag mode. Lieu muet dragging refers to dragging in a way that preserves some regularities in the geometrical object. The researchers reported that analyzing these different types of dragging modalities provides insights into how students are switching between reasoning empirically and theoretically. This connection between empirical evidence and theory was also analyzed by Chazan (1993) with a focus on how students made use of measures. Chazan, who conducted research with students using a non-dynamic geometric construction program, found that students believed that empirical evidence such as measures, computer-generated drawings or pencil and paper drawings were sufficient to prove a statement true for all cases. Students believed that empirical evidence was proof. The case study analysis for the current study examined students' interpretation and use of technology including students' use of capacities of the dynamic tool, such as dragging and measures as they were learning about geometric transformations

### Methods

The participants for the study were selected from a class of seventeen high school Honors Geometry students. Six of the students, who reflected a range of mathematical abilities and technological familiarity, were selected to serve as participants. The van

Hiele Geometry test (Usiskin, 1982) was administered at the beginning of the study and it revealed that the six selected participants were at or above level 3. The test was administered only at the beginning of the study to provide additional data for selecting participants. Case studies were conducted on four of the six participants, Jennifer, Kevin, Ben, and Sarah, for whom data seemed to hold the most promise in addressing the research questions.

During the 1999-2000 school year the researcher taught a seven-week unit on geometric transformations to all students in the Honors Geometry class. The instructional unit was based upon curriculum materials written by a team of mathematics educators at The Pennsylvania State University and University of Iowa through the CAS-Intensive Mathematics Project (Heid, Zbiek, Blume & Choate, 1999). The materials are written with the assumption that students have constant access to dynamic geometry tools and computer algebra systems.

### **Data Sources and Analysis**

Major sources of data were verbatim transcripts of whole class discussions, the six participants working in small groups, task-based interviews, photocopies of written work, and field notes. Data were collected during 28 classes and during 3 task-based interviews conducted with each participant prior to, in the middle, and at the completion of the instructional unit. The activities in which students engaged while working on the computers during class and interviews were recorded directly using a ProScan converter connected from the computer to a videocassette-recording device.

Subsequent to collection of all data, the researcher engaged in an in-depth case analysis, which involved developing characterizations of individual students' understandings of geometric transformations and their use of technology. An analysis across individuals was also conducted to identify cross-cutting themes related to the research question. The case study method (Stake, 1995) and constant comparison method (Glaser & Strauss, 1967; Strauss & Corbin, 1990) were used. Results from the cross-case analysis will be presented.

### **Results**

The ways in which the computer mediated students' understandings of geometric transformations was analyzed by focusing on students' purposes for using the technology, when they were allowed to make choices about its use, and determining how such uses contributed to or limited their problem solving efforts. Three themes related to the role of technology in students' understandings of geometric transformations are reported. They include students' understandings and use of dragging, students' uses and interpretations of measures, and students' uses and interpretations of dynamic sketches.

#### **Students' Understandings and Uses of Dragging**

The purposes for which students used the dragging modality were to test a construction by applying the drag test, to verify a conjecture, to observe behaviors of

points under the drag mode, and to search for invariances. The purposes were sometimes explicitly stated by the student and sometimes inferred by the researcher from the actions and statements of the student. An example of students' use of the drag test will be presented.

### **What is dragging?**

When one drags a point in a dynamic sketch he or she is, in essence, sampling points in the plane. From this perspective, a point is like a variable. As it is dragged in the plane it is assigned different coordinates. The label of the point is similar to the name of a variable. The name of the point does not have significance. Sarah's understandings of the effects of dragging on points appeared to be related to how she viewed the appearance of the point. Because the point retained its label and looked the same, she stated that she believed the point had not changed even though the coordinates of the point had changed.

During a whole class discussion that took place in class 9 the researcher asked students to think about what was happening when they were dragging various objects within a dynamic sketch. In particular, the researcher asked students to consider the reflection of points A, B, and C, over line DE. The image points, A', B', and C' were drawn on the board and the researcher asked the students to think about the reflection in terms of input, output, and parameter. Students were asked to consider what was being varied (input, output, or parameter) if line DE was dragged. Because the labels of the two points on the line (D and E) remained the same, students often thought they were considering the same object and had a difficult time thinking about moving the line of reflection as varying the parameter. Later in this same class, students were asked to describe if dragging a pre-image point was most similar to changing the input, output, or parameter. Sarah's partner said that she was unsure how dragging this point allowed her to examine different input output pairs.

Sarah's partner: Well, how do you change it though? Because all you're doing is moving it.

Researcher: Right. So, by moving...

Sarah: But that means it's in a different place than it originally was. You didn't like change the point name or anything. [Class 9, 302-308]

The fact that the name of the point remained the same seemed to suggest to Sarah and her partner that it was, in fact, the same point. They seemed focus on the material representation of the point (the drawing) rather than reasoning about the theoretical definition of point. The students seemed to believe that simply changing the point's location did not cause it to vary. However, when the researcher suggested students consider the coordinates of the points, something that would vary as the point was dragged, they seemed to begin reasoning about dragging a point as varying the input (or output). The use of coordinates seemed to support their reasoning about points

as variables. Researchers have reported that the concept of variable is difficult for algebra students to understand (Boers-van Oosterum, 1990). It is not surprising that Sarah and her partner had difficulty attributing characteristics of algebraic variables to geometrical points.

### The Use of the Drag Test

Although all four students were at first hesitant about dragging, during the course of the study they developed different purposes for dragging. One purpose involved dragging to check whether the construction they created maintained the properties of the figure they were constructing. Hoyles and Noss (1994) introduced this type of drag test to students to determine whether they had created a figure that is messable (does not maintain its properties when dragged). All four students in the current study used the drag mode for this purpose. However, the way in which students interpreted the results of the drag test varied. Some students used the drag test to determine which properties needed to be included in their sketch and used this information to modify their construction. Other students simply described the results of the drag test (e.g., "it is no longer a rectangle") without focusing on properties and experienced more difficulties in creating a correctly constructed figure. An example from the second interview will be used to contrast the two different interpretations that were made from the drag test. During the second interview, the researcher asked students to construct a rectangle using at least one reflection and other construction menu commands as needed. An example of the first interpretation of the drag test occurred with Kevin. He drew (rather than constructed) a vertical line  $CD$  and a vertical segment  $AB$ . He reflected the segment over the line which he marked as a mirror line and connected pre-image/image points as shown in Figure 1.

Kevin dragged one of the endpoints and noted that because the object was no longer a rectangle his construction method would not work. Kevin explained that in order for the construction to work, segment  $AB$  needed to always remain parallel to the line of reflection (line  $CD$ ). The fact that the drag test failed seemed to prompt Kevin to step back and think about the properties of a rectangle. After he considered what was needed he explained the condition

Figure 1. The "rectangle" Kevin produced during the second interview.

that the segment be parallel to the line of reflection was needed. This is contrasted with Sarah who constructed a rectangle using the same method. However, when she applied the drag test, she explained that her construction did not work because the rectangle became a trapezoid. Rather than focus on the properties that were needed to construct a rectangle (opposite parallel sides), as Kevin did, Sarah simply described what happened in her drawing when she dragged. Students' interpretations and uses of the dragging feature of the technology seemed to be related to the extent to which they made use of their mathematical understandings as a filter through which the irrelevant aspects of the sketches could be removed allowing them to focus on the more important features. The use of mathematical understandings was also critical to their use and interpretations of measures.

### **Students' Uses and Interpretations of Measures**

GSP allows students to measure geometric objects (e.g., line segments, angles) and updates those measures dynamically as objects are changed by dragging. The purposes for which students used measures included exploring relationships, creating and verifying conjectures, and checking the correctness of a construction. An example that illustrates the first three purposes and another example to illustrate the last purpose will be provided.

#### **Use of Measures to Explore Relationships, Create and Verify Conjectures**

An example of different ways in which students used measures to explore relationships within a sketch and to create conjectures occurred when students were asked to determine to what single transformation the composition of two given translations is equivalent (See Figure 2.). Jennifer and Ben created triangle ABC, translated it by vector DE (which Ben had drawn using the ray tool) and then translated its image by vector FG (Jennifer suggested to Ben that he draw this using the segment tool). They conjectured that the composition of two translations was equivalent to a single translation using vector AA''. The researcher challenged them to determine how vector AA'' was related to the original two vectors. To investigate this, Ben seemed focused on finding a relationship among measures without focusing on what the measures represented and whether they made sense in terms of the relationship they were exploring. He measured the magnitudes and slopes of the vectors and after determining that it was not possible to write one as a linear combination of the other two he began to look for other objects to measure.

Ben: Could the distance between, here and right here, could (they) be equal [Ben drew segments AF and AD to measure the distance from A to F and A to D]? Could they be equal maybe?

Jennifer: I'm not sure of that. See, I'm not sure that that would matter. Hmm. And it's not like it matters where these [vectors] are. So that distance [A to F and A to D] shouldn't matter. You can get rid of those. [Ben deleted segments AF and AD] Okay, well, let's figure out what counts here. [Class 12, 333-340]

$DE = 3.67 \text{ cm}$   
 $FG = 4.28 \text{ cm}$   
 $AA'' = 7.15 \text{ cm}$   
 $\text{Slope } \overline{FG} = -1.30$   
 $\text{Slope } \overline{DE} = -0.01$   
 $\text{Slope } \overline{AA''} = -0.54$   
 $m \overline{AF} = 5.47 \text{ cm}$   
 $m \overline{AD} = 4.66 \text{ cm}$

Figure 2. The dynamic sketch Ben and Jennifer created while exploring the composition of translations

Jennifer suggested to Ben that he drag segment  $FG$  so that point  $F$  coincided with point  $E$ . She then directed Ben to create segment  $DG$  and measure its slope. She immediately noticed that its slope was the same as the slope of segment  $AA''$ . Although these students had not been taught how to add two vectors, Jennifer was able to create this on her own by thinking about the composition of two translations. Perhaps, because Jennifer was able to step away from the problem and think about what information was relevant she was able to notice this relationship among the vectors. Her focus on the relevant features in the sketch and her purposeful use of measures and dragging which was guided by her understandings of transformations allowed her to create and test her conjecture about the composition of two translations. However, the use of measures and Ben's focus on the quantities rather than the objects to which they referred seemed to constrain his thinking about the sum of two vectors.

### Use of Measures to Test the Correctness of a Construction

Several students used measures to test whether or not their construction, which they often created by reasoning about properties, was correct. To illustrate this approach an example from Jennifer's work will be provided. Jennifer was asked by the researcher to explain how she could construct a square using rotations on GSP, during the second interview. Jennifer explained that she would start with segment  $AB$  mark  $A$  as the center and rotate point  $B$  90 degrees about  $A$ . She explained that then she would mark  $B$  as the center of rotation and she would rotate point  $A$  270 degrees about point  $B$ . She said then she would "connect the dots" and the resulting figure would be

a square. She explained that all the angles would measure 90 and all the sides would have equal lengths because a rotation preserves the lengths of segments. However, after she executed this construction she measured the sides to make sure the lengths were equal, as shown in Figure 3. She then explained that if she measured opposite angles and they were both 90 then the other two angles would also measure 90.

$$m \overline{B'A'} = 3.78 \text{ cm}$$

$$j' = 3.78 \text{ cm}$$

$$m \overline{AB} = 3.78 \text{ cm}$$

$$j' = 3.78 \text{ cm}$$

$$m\angle B'AB = 90.00^\circ$$

$$m\angle BA'B' = 90.00^\circ$$

Figure 3. The square Jennifer constructed using *Geometer's Sketchpad*

Jennifer's decision to measure only two angles seemed to be based on her assumption that the quadrilateral was a rhombus because the measures she found were all equal. She seemed to take the empirical evidence as given information from which she deduced what other measures would be sufficient to gather. There seemed to be an interplay between her reasoning from empirical results and reasoning about properties of squares. Her reasoning was not deductive and not solely empirical. She seemed to employ a type of pseudo-deductive reasoning.

Jennifer appeared to use measurements to check the construction she created even though

she explained why the construction should result in a square based on the properties of rotations. The measures might have been used to provide further corroborating evidence to assure her that she had constructed a square. In this way their availability within the tool seemed to support her problem solving. The measures also might have been taken to illustrate to the researcher that she had constructed a square.

### Interpretations and Uses of Dynamic Sketches

Students developed a variety of ways of interpreting and using dynamic sketches. One student treated the dynamic environment as an electronic drawing board (e.g., MacDraw). All four initially interpreted the dynamic sketches statically and all four used strategies that were described by the researcher as reactive or proactive. Whether students were using premade sketches or sketches from "scratch" did not seem to influence their use of reactive or proactive strategy. Rather, their focus on figure or drawing seemed to be connected to the type of strategy employed.

## Reactive and Proactive Strategies

The analysis revealed that students appeared to employ two different types of strategies when working with the computer: reactive and proactive. Reactive strategies were strategies that involved performing an action and then determining the next action based on what appeared on the computer screen. The ways in which the student determined the next action was not based on their understandings of mathematics but rather the next action seemed to be determined by using a trial and error approach. Reactive strategies seemed to be based in reasoning about the visual appearances offered by the computer (drawings). Both Kevin and Sarah, when asked to construct an equilateral triangle using rotations appeared to reason from the visual feedback that was generated by the computer. Their approach to these problems seemed to be characterized as a process that involved marking a center, rotating an object through some number of degrees, and then viewing the screen to determine if the angle measure or center needed to be adjusted. Rather than reason about the properties of the object they were trying to construct and relations to the rotation they were applying they seemed to employ a guess and test strategy.

Proactive strategies were characterized by a student having a plan in mind about how they were going to use the computer and were guided by students' understandings of geometrical properties and relations (figures). For example, the researcher presented Jennifer with a pre-constructed sketch (See Figure 4.) and told Jennifer that a single transformation was applied to all points in the plane.

Jennifer was asked to determine what transformation was applied. To do so, Jennifer carefully dragged one of the two corresponding pre-image/image points until each pair coincided (See Figure 5.).

She used the pattern of the coinciding pre-image/image pairs to create a line segment that she said represented the line of reflection. She stated that the transformation that was applied was a reflection. Jennifer's understandings about fixed points appeared to guide her dragging activities that were afforded to her by the technology.

### Discussion

A characteristic of students' reasoning and problem-solving activities as they came to understand transfor-

Figure 4. A picture of the matching task.

Figure 5. The diagram after Jennifer dragged pre-image (image) points until they coincided with their corresponding image point (pre-image)

mations in a technological environment included the ways in which they used different feature of the technology including the use of dragging and measures. Students' uses of these features were related to and influenced by their mathematical understandings. Their understandings were also influenced by students' engagement in anticipating the results of their actions and reflecting on what was produced by those actions using their mathematical understandings. The lack of anticipation or reflection was demonstrated by students who often relied on visual information to provide cues that allowed them to determine their next action. The availability of this visual information offered by the technology seemed to constrain students' reasoning about transformations; students tended to reason about the material drawing rather than the geometrical properties. On the other hand, students who engaged in anticipation and reflection

and drew upon their mathematical understandings to interpret visual information generated by the computer seemed to reason about the figure. The technology seemed to support students' developing understandings of transformations by allowing students to use proactive strategies employing measures and dragging. Many researchers, teachers, and reform documents suggest that the use of technology promotes students' understandings of mathematics and recommend that technology be incorporated into the teaching and learning of mathematics.

Relatively little is known about how students use technology and what understandings they develop when it is used to learn new mathematical concepts. This study provides evidence to support that technology can promote students' understandings of mathematics and it provides insights into the ways in which students interpreted technological results and used technology as they were learning. There is still much more that needs to be understood about the complexities that are involved when technology is used by teachers and by students in the learning and teaching of mathematics.

# COORDINATING MEDIATION OF ACTIVITY IN THE LEARNING OF GEOMETRICAL TRANSFORMATIONS

Verónica Hoyos  
CAEM, Universidad Pedagógica Nacional  
vhoyosa@upn.mx

This is an attempt to contribute in a research perspective related to the use of computerized scenarios and the introduction of historical contexts (Bartolini, 1998; Bartolini & Boero, 1998; Boero, Pedemonte & Robotti, 1997) in the search of significant tools (Confrey, 1993) for mathematical learning. Particularly we are presenting evidence, referring to the manner in which students acquired coordinating experiences, obtained through activities in connection with the scenarios and some set up tasks. Collective and group activities designed for eighteen students aged fourteen carried out within a teaching experiment based on the implementation of two learning scenarios focused on elementary geometrical transformations. In these scenarios, activity mediation through cultural devices became useful to promote intuition and objectification of geometrical properties in play; both processes become essential for developing discourse from a communicational approach to mathematical learning (Sfard, 2001).

## Theoretical Framework

From an educational perspective derived from the psychological school of Vygotsky, a great number of arguments have resulted (Bartolini & Boero, 1998; Boero et al., 1997; Mariotti et al., 1997) in favor of the introduction or the use of certain kind of mechanisms to increase the understanding of mathematical notions and ideas in the classroom, as the manipulation of large pantographs that permit the tracing of drawings or exact designs by the students.

Besides, microworlds and computer science have allowed to glimpse improvement in diverse educational problems, like succeeding in the control of the execution of solving algorithmic procedures, or the students' possibility to assess used solving methods (Hoyos, Capponi & Geneves, 1998; Hoyos, 1999); or "real" implementation of novel work proposals (Jørgensen, 1999).

The fundamental role of the tools as mediation for educational purposes can be recovered to a large extent by the socio-cultural perspective of the learning research. In fact, one of the basis of the investigation framework from these standpoint, consists of the assumption that notion and mediation are inherently related (Werstch, Del Rio & Alvarez, 1995, p. 19), so that:

"Experience does not go on simple inside a person... in a word we live from birth to death in a world of persons and things which is in a large measure what it is because what has been done and transmitted from previous human activities. When this fact is ignored, experience is treated as if it were something, which goes on exclusively inside an individual body and mind. It ought not to be necessary to say that experience does not occur in a vacuum. There are sources

outside an individual which give rise to experience". (John Dewey, 1938/1933, p. 39, quoted in Werstch et al., 1995, p.190)

Finally, in the implementation of the learning experiment that is presented in this paper, the relationship was basically aimed –in the context of tasks designed for that effect, within the manipulation of significant cultural artifacts and the promotion of mathematical speech in the classroom. According to Sfard (2001), “communication should be viewed not as a mere aid to thinking, but as almost tantamount to the thinking itself” (Sfard, 2001, p.23).

So, a mathematical learning investigation based on communication taking place in the classroom, should investigate the development of a mathematical discourse focusing three main aspects: a) Vocabulary used by students during work sessions; b) Mediation artifacts (even though Sfard only mentions explicitly visual mediation); c) Meta-discursive rules. (Sfard, 2001, p. 28).

### **Aims, Methodology and Results**

In this work, it is interesting to point out the way in which students modify their discursive actions. In order to do that, we have observed how pupils approach new mathematical terms, using scripts for the activity, the manipulation (and support) of certain cultural artifacts, and describing their accomplished requested tasks. Particularly, it was interesting to analyze the different descriptions that are carried out at the end of the performed activity. From our point of view, these descriptions reflect how pupils coordinate their obtained experiences.

With this purpose in mind we set up two learning scenarios, which involved, in the first one, an introductory exploration of the geometrical transformation topic using the menu comprised in Cabri II.

The second scenario consisted basically in the manipulation of large pantographs, which allowed students to trace drawings guided by specific geometrical configurations underlying in the articulation machines.

In total, 10 practical, 50 minute long work sessions were carried out in April 2001. In them participated 18 students, 14 years old, attending junior high school (9<sup>th</sup> level).

Actually, in the first scenario, the script used in order to introduce the topic of geometrical transformations in Cabri-II, allow students to a first encounter with the terms in use. It is important to mention here that the “*Help*” command in Cabri-II was activated at all times. When the *Help* command is activated, Cabri-II shows on the screen a scientific description of all necessary requirements involved in a certain application or construction, and the order that some choices or constructions might be done.

It was extremely important to provide students with scripts that indicated to appeal to the *Help* command so, they would be able to access to a first perception of the objects and relationships involved in a geometrical transformation, to a visual configuration of properties and relations between them.

### Templates and Mediation Artifacts

Next, we will show the first prototypical student's answer. It was obtained when a description of the geometrical configuration was required and resulted from activating the Cabri-II *Dilation* command:

Abraham: Let's say if we are reflecting... Well, we are drawing a line going through this point [the dilation centre point], it is going to pass through the dilated, by the reflected figure. As it is divided into pieces [i.e. tracing the segments going from the dilation centre point to a point P on an initial object, and from the point P to point P', P' the dilated point, or image from P] then, the traced segments are going to be on a straight line.

We can observe that even as Abraham is using the mathematical terms in a very diffuse manner, it is possible to show up what was used when answering –because he is pointing at the figure produced. So, to understand that Abraham is expressing the alignment property of dilation between corresponding points P and P'.

A first analysis carried out at students of standard level performance tells us the following. In general, even the students after working within Cabri-II could visualize some relationship and properties, these were enunciated in a cut way, formulated without a description of the situation between the designed figure in question and its image under the dilation.

Similarly, relating to the other first requested student's answers, they were very vague too. For example, when they were asked to observe the effect of moving any of the points P in initial triangle and describe what was happening to the P' point on the reflection image. Most of the students could not determine or characterize in any way (by the orientation, for example) the different trajectories perceived. In general, the answers were of the type "a point moves with the other". However, that answer does not characterize any of the transformations because it is valid for all of them.

What actually happens, for example, comparing the reflection and translation cases, is that in a triangle drawn figure we set a point P and, when we move it clockwise, then, in the reflected figure the movement of the P' point is against-clockwise. While the effect of moving P under the translation geometrical transformation is always in the same orientation. (See Fig. 1, and Fig. 2 at the end of this paper.)

In fact, the students "*have just entered the template-driven phase*" (Sfard, 2001, p.33). They were trying a new way of speech about certain concepts or notions, using words and phrases supplied by the script and through the Cabri-II *Help* command. They were trying their first use of a template at hand, and their later elaboration of some phrases was, in fact, restraint.

It is worth to mentioning here, one hypothesis working there. It has been applied in both learning scenarios –and in the type of didactic situations instrumented there. The hypothesis is that a crucial point in order to produce learning results it is constituted by enunciation of the underlying mathematical properties in the drawing (Laborde, 1993). Such enunciation could be established through arithmetical relations

between drawing's properties, or textual expression of general properties noticed in the tracings –question facilitated by the software dynamism (in case of computer support), or from geometrical configurations of the material support provided to students; or finding algebraic terms or equations.

In general, any of the required enunciation will depend on the background and academic level of the student, and on the comprehension of the properties underlying the drawing carried out.

In reference to the second scenario, pupils were required to manipulate some pantographs brought into the classroom in order to make students aware of geometrical properties involved in their drawing. In this scenario, the whole script used consisted only in general instructions to explore and describe the perceived relationships or geometrical properties between tracings carried out.

Students were asked to draw a figure manually, guiding one end of the pantograph. Therefore, in this way, they simultaneously obtained two figures, one draw by themselves and another one made by the machine articulations. Next, they were asked to describe the relationship between the object drawn by them and the reproduction effected by the machine. They were also asked to express what was the transformation implied.

Next, we will show the type of descriptions accomplished by the students at the end of the work sequence in the second scenario –following the manipulation of the pantographs, when they were asked to describe what they had just obtained by the accomplishment of the given task.

Interviewer (I): What did you do?

Dulce: This is the original figure, this point is the one that traces the original figure [being point A, the one that is nearer to the dilation centre point O], this is the resulting figure; these figures...

Interviewer: Ok. And how did you draw them? Show me, [Coral moves a ruler, bringing it near the drawn figure and point A]

Interviewer: No, but how did you draw it with the machine?

Dulce: [Dulce moves the machine and explains] Following this point [A], for example, drawing, and this one follows [point B]

Coral: And it forms a bigger figure.

Interviewer: Ok.

...

Interviewer: Ok, all right. But, could we know, let's say, what I'm looking at here is that this figure is smaller than the other one, isn't? But could we know how small is it? Let's say it is what part? Is it half, or one fourth, or what part is it?

- Dulce: (Dulce measures the sides of the drawn squares with a ruler)  
Half.
- Interviewer: It's half. How do you know?
- Coral: It's the fourth part.
- Dulce: Because we measured it.
- Interviewer: Because you measured... And then what?
- Dulce: This one is 3.5 and this one is 7 [Dulce is placing the ruler along the sides of the drawn squares].
- ...
- Interviewer: The side, the side measures half.
- Coral: It measures half; and on this side [on one of the perpendicular sides of the resulting square or image], again it measures half.
- Interviewer: And then, I would have...
- Dulce: The figure
- Coral: The figure is formed, and it is about the fourth part of the original square...Of the resulting square [she is referring to the dilated square].

As in the case of Abraham the students Coral and Dulce visualized the linear relationship existing between O (the dilation centre point), P and P' (initial and dilated point, respectively). However, in this case we can observe a great improvement in the mathematical use of terms. Because the students perceive a relationship between both figures, the initial and the dilated (remember that Coral almost immediately said "And it forms a bigger figure"), and they arrive to establish a numerical relationship between the measurements and the area of the drawn figures.

It is probable that these students were near to establishing all the numerical inter-relationship of proportionality implicit in the drawn figures.

In doing that, dilation might become represented by certain new mathematical terms, those numerical interrelationships emerged from their activities.

### **Practical Working Sessions at School**

The teaching of school mathematics in junior high school in Mexico has, among its aims, more than learning rules and procedures, to promote understanding and problem solving. In the same way, intends that classroom activity let to emerge conjectural processes, communication and validating (cf. Alarcón, et al., 1994; National Council of Teachers of Mathematics [NCTM], 2000).

While from the declarative point of view, validating knowledge or negotiation of meaning has always had a privileged place within the framework in the constructivist

knowledge. In general, within the scholar practice in Mexico this has been limited to a formal institutionalized knowledge performed mainly by the teacher.

Besides, that most teaching experiments have been pursued is to report mathematical subjectivities or conceptualizations reached through small groups, or pupil-teacher interaction.

However, a collective negotiation of such intersubjectivities needs to plan a long-term individual and collective learning. It is also needed, a collaborative and supportive substructure of research which is more complex than the one centred on individual or in small groups learning.

Little or none are the efforts in our system aimed to set up a collective negotiation of meaning. Nonetheless, the validation or such collective negotiation postulates are the cornerstone of the current curriculum.

Now days, in the context of the everyday educational practice, Mexican pupils attend, five days a week, 50 minutes daily, to mathematics lessons. These courses are usually taken in the same classroom, with the same teacher and, with no other tools but pencil and paper.

Thus, one of the goals of the project on which this paper is based (CONACYT, # 30430-S) was to look for grounds favoring to alternate practical and normal lessons for the quality improvement in the learning of mathematics in Mexico.

In particular, the empirical results presented in this paper hold that practical working sessions similarly to those presented here must take place at school everyday, as it is noticeable the behavior of the girls who participated in the experiment on equal terms as boys. Remember that the performance of the pupils Coral and Dulce is prototypical of the standard reached in class. (See Fig. 3 at the end of this paper).

Regarding the participation on equal terms Szendrei (1996) says that the role of the use of concrete materials (common tools and educative materials) by pupils of both gender is that of facilitate equal development of mathematical skills in both, boys and girls of the same age at school. Skills that are not equally well developed through out-of-class experience (Szendrei, 1996, p.427).

Supporting Szendrei's view, there are careful analysis of the data collected during the Second International Mathematics Study (SIMS), carried out by the International Association for the Evaluation of Educational Achievement between 1982-83. These analysis bring out that there are not important sex differences regarding the mathematical advances among 13 year olds:

"... It appears that girls and boys assimilate the subject matter taught in class equally well in Arithmetic, Algebra and Statistics. Thus it seems reasonable to hypothesize that sex differences at that age, when they exist, are due to out-of-class experiences and psychosocial processes rather than to biological differences". (Hanna, 1989, quoted by Szendrei, 1996, p.427)

As a matter of fact, in various societies girls (Szendrei, 1996, p.429) are forced to

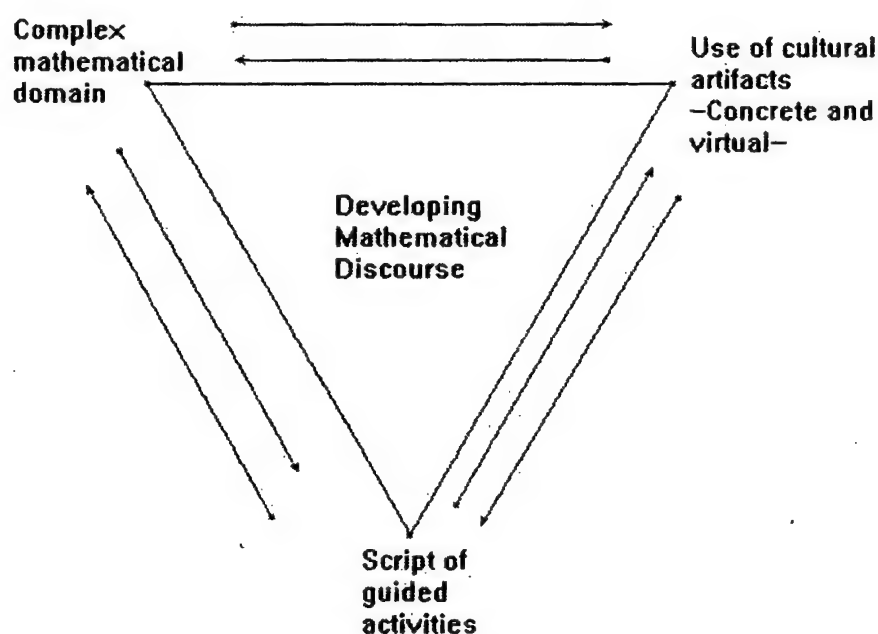

play only girls games. Therefore, activities in the mathematics lesson using concrete materials contribute to give both girls and boys an equal chance for development.

It is also important to point out again, the fact that in order to carry out practical working sessions on mathematics at school, different concrete materials, as well as new technologies, like computers, internet access, calculators, etc. must be used. In the same way, it is of great importance to have scripts and or working prototype sequences for pupils, similar to those here mentioned, which should be prepared to accomplish complex tasks on mathematics and to be used as templates for developing discourse in the classroom.

Summarizing, a didactical hypothesis emerged from this work is that it is probable that the learning scenarios based on the mentioned elements will allow the advance and set up of mathematical communication within the classroom. These principal elements were the following: (a) The use of scripts –as templates, to guide activities; (b) [In order to] Manipulate cultural materials or artifacts (concrete and virtual); (c) Working on mathematical complex domains.

Finally, by means of this teaching experiment, it was possible to insert in school, in a successful way both previously mentioned learning scenarios during a normal mathematics course in a government school. These grounds the fact that practical lessons conformed as scenarios mentioned here might be very welcome for school actors. Such practical lessons would be complementary to the traditional mathematical courses in our country, which are frequently the only ones carried out all the way in our educational system.

*Figure 1.* Didactical elements to promote mathematical discourse within the classroom.

### Conclusions

The discourse or utilization forms of mathematical terms in use by Abraham allowed taking on account an intuition process related to mathematical notions and properties in use. Such intuition was characterized by a diffused or weak use of new terms, which in our point of view refers to one of the characteristics of phase one of the developing process of discourse in the classroom (Sfard, 2001, p.32). This characteristic is that of the use of signifiers by templates, in this case those provided by the scenario script.

As a complement, the derived objectification from the manipulation of articulated machines (or pantographs) conducted to a greater comprehension relating to a mathematical use of the terms. The evidences of the establishment of a numerical relation between the drawn figures might be given account of how the terms or symbols in use would become appropriate representations of drawing.

Finally, we only want to underline the didactical possibilities emerged from these empirical findings, as a elemental base for generating mathematical thinking and discourse. That is to say, it is probable that a base to a suitable mathematical meaning of a topic in question could be to establish through a sequence of actions consisting of the following steps: a) To start with the emergence of intuitions by means of activities within the dynamical software. b) To continue to the objectification of the geometrical properties at stake, by means of activity through cultural artifacts. c) To communicate (with the support offered by the software dynamism and the use of new technologies) strategies and solutions to possible proposed problems.

# **DEVELOPING PRESERVICE TEACHERS' MATHEMATICAL REASONING AND PROOF ABILITIES IN THE GEOMETER'S SKETCHPAD ENVIRONMENT**

Zhonghong Jiang  
Florida International University  
Jiangz@fiu.edu

This study investigated the actual learning processes of two preservice teachers as they explored geometry problems with dynamic geometry software and the effects of using the software on developing their mathematical reasoning and proof abilities. A constructivist teaching experiment was designed and implemented for the investigation. Through participating in the study, the subjects developed a new learning style—exploring problem situations through a learning process characterized by initial conjecture – investigation – more thoughtful conjecture – verification (or proof) – proof (or verification). They changed their conceptions of mathematics and mathematics teaching as well. The Geometer's Sketchpad (a dynamic geometry software package) was found to be an excellent teaching and learning tool that can enhance students' mathematical reasoning and proof abilities.

A research study was conducted in the Fall semester 2001 within the course "Learning Mathematics with Technology" (MAE 3651) for secondary school mathematics preservice teachers at Florida International University. The goal of the course in which the subjects were enrolled during this study is to help the preservice teachers experience learning mathematics with technology, determine important content areas for the secondary school mathematics curriculum and develop competency in these content areas. Using dynamic geometry software to revisit high school geometry is a major focus of the course.

## **The Purpose of the Research**

The purpose of the research was to investigate the actual learning processes of the preservice teachers as they explored geometry problems with dynamic geometry software and to find the effects of the use of dynamic geometry software on developing their mathematical reasoning and proof abilities.

## **Conceptual Framework**

The conceptual framework of this study came out of the constructivist perspective that knowledge is not passively received from the teacher but actively constructed by the learners themselves, the van Hiele model of geometric thinking, and the research on mathematical reasoning and proof. According to van Hiele (1986), students progress in geometric thinking through a taxonomy of levels, and progress from one level to the next higher level is dependent on the nature of the instruction provided to students. The van Hiele levels are numbered differently in various sources. Based on the numbering system used by Battista & Clements (1995), the levels are: Level 1 - visual, Level 2 - descriptive / analytic, Level 3 - abstract / relational, Level 4 - formal deduc-

tion, and Level 5 – rigor / metamathematical. de Villiers (1987) suggests that deductive reasoning in geometry first occurs at level 3 when the network of logical relations between properties of concepts is established. He claims that because students at levels 1 or 2 do not doubt the validity of their empirical observations, formal proof is meaningless to them - they see it as justifying the obvious (Battista & Clements, 1995). Other researchers (Senk, 1987; Van Dormolen, 1977) give similar suggestions.

### **Design and Procedure**

A constructivist teaching experiment was designed and implemented for the investigation. During the teaching experiment, I attempted to provide opportunities for the students (preservice teachers, the same hereafter with only a few exceptions) to learn by judiciously selecting tasks, posing questions, and encouraging active explorations. The study lasted for ten weeks when the course concentrated on geometry topics using the Geometer's Sketchpad (GSP), a dynamic geometry software package. Since the students' detailed changes and growth in their learning processes were the focus of the investigation, two students were selected from the MAE 3651 class to participate in the study. They did not join the big class during the ten weeks except for the first class session in which a pre-test was administered. Teaching interviews (two times a week with 75 minutes each time) were conducted for them, sometimes individually, and sometimes in a pair (for cooperative learning purposes). The time for the subjects to learn geometry and the problems for them to explore were basically the same as those for the big class. The difference between the two settings was that there was much more one-on-one interaction between me as the instructor and the subjects in the teaching interviews. The two subjects were selected based on both their willingness of participation and their different thinking levels in the van Hiele model.

The study consisted of three phases. Phase 1 was the pre-test. Phase 2 consisted of nine-week teaching interviews. Phase 3 was the post-test.

#### **The Pre-test**

For the pre-test, I used 30 questions - 20 questions selected from Mayberry's (1981) instrument and 10 questions that I had devised - to assess the student's van Hiele levels of geometric thinking. All questions dealt with triangles and quadrilaterals. The 10 questions that I had devised looked more on whether a student can do simple proofs. The 10 questions and the criteria for scoring were developed with the same structure as that of Mayberry's instrument. From among the students who were interested in participating in the study, a male student (Fred) and a female student (Lisa) were chosen. It was found that Lisa was at level 3 and Fred was at level 2 in the van Hiele model.

#### **The Teaching Interview**

The teaching interviews for each of the two subjects explored the detailed processes in which the students' problem solving, mathematical reasoning, and proof abilities were enhanced. The subjects worked on the assigned activities using GSP as

a tool. I interacted with them by probing with questions, and giving hints only when they needed help.

The problem situations used for the interviews were designed based on the following considerations: 1) The tasks assigned to the subjects should “focus on important mathematics” (NCTM, 2000, p.15); 2) These tasks should be both challenging and consistent with the subjects’ van Hiele levels of geometric thinking; 3) The sequence of tasks should help the subjects gradually progress from lower levels of geometric thinking to higher levels; 4) The tasks should emphasize the subjects’ active hands-on activities with the dynamic geometry software to assist their mathematical thinking; and 5) The tasks should allow the subjects to generate feedback from which they can judge the efficacy of their methods of thinking. Nine sets of problems were designed and assigned to the subjects during the interview sessions. Solving these problems required the grasp of important concepts and relationships related to the following three topics: Triangles, Quadrilaterals/Polygons, and Circles. Since a proof-oriented geometry course requires thinking at least at level 3 in the van Hiele hierarchy (Battista & Clements, 1995), the problems (especially the problems at the early stage of the interviews) given to Fred didn’t require formal proofs but informal arguments, while all problems given to Lisa required both intensive investigations and formal proofs. The problems were sequenced so that the level of sophistication and difficulty of problem contexts increased gradually. Taking full advantage of the dynamic, multiple, linked representations given by GSP was encouraged in explorations of the problems.

### **The Post-test**

At the end of the ten weeks, the subjects took a written examination (with the other students in class) and an additional post-test. The post-test given to Fred was the same as the pre-test except for three items, which were new activities for him and went beyond any of the tasks he encountered during the interview sessions. The post-test given to Lisa consisted of 10 proof-oriented questions or problems.

### **Data Collection and Analysis**

Each teaching interview was videotaped. All significant parts of the videotapes were transcribed. Careful notes were taken for all interview sessions and related after-session discussions. The answer sheets of the pre-test and the post-test, the computer files on the disks, as well as the written work (assignments and tests/exams) and comments completed by the students in each interview session, were also collected for analysis.

A constant comparison approach (Glaser & Strauss, 1967) was used in this study for the data analysis. This method of analysis is inductive - it moves from data to tentative theory, to new data, to refined theory. The transcripts of the videotapes and other data were analyzed during interview sessions and after all sessions were completed. These analyses took the form of editing data with commentaries. The commentaries

depicted the story lines of the corresponding students' progression through the sessions and revealed the critical developmental points of the students.

## Results

### A New Learning Style

In the teaching interviews, the subjects were encouraged to explore each problem situation through a learning process characterized by initial conjecture - investigation - more thoughtful conjecture - verification (or proof) - proof (or verification). This learning process effectively facilitated the subjects' development of mathematical reasoning and proof abilities.

During the third week of Phase 2, the subjects were assigned to solve the problem below:

A road is proposed that will connect two towns A and B on opposite sides of a river. The road will cross the river in a bridge that is perpendicular to the riverbanks. Where should the bridge be placed so as to minimize the total length of the road?

First, the subjects were encouraged to give their initial conjectures. Lisa used her knowledge from a previous problem in which the river was simply a line (river width ignored). In that case, the shortest path was the straight line segment from point A to point B. So, she automatically assumed the same approach for this problem. She drew a straight line connecting points A and B. This time, however, since the river had a width, the line intersected the river at two points. She decided to find the midpoint of the segment determined by these two intersection points. She then went on to conjecture that it was the segment through this midpoint perpendicular to the riverbanks that would give the shortest path from A to B. Fred had a different conjecture. He believed that the bridge on the shortest path should lie on the line passing through the midpoint of segment AB and perpendicular to the riverbanks.

The subjects then tested their conjectures through experimentation with GSP. Using the dynamic feature of GSP, Lisa was able to construct an arbitrary path and move it along the river until she found the shortest path (path AMNB in Figure 1) by using the Measure tool. This path disproved her initial conjecture. Fred "located" the shortest path in a similar way. His conjecture was also found to be incorrect.

However, the shortest path that was "located" was not the real path that must be constructed. The subjects were led to carefully observe the "located" shortest path, and try to find its characteristics. Through observation and checking by doing necessary measurements, Lisa found that the most important characteristic of the path was segment AM // segment NB. Because of this, if AM was moved down by the width of the river, then AM and NB lied on the same line. In addition, point N that located the bridge on the shortest path was the intersection point of this line and the bottom riverbank. This analysis revealed an idea to construct the shortest path - Translate point A by vector  $XX'$  (Segment  $XX'$  in Figure 1 represents the river width.) to locate point

Figure 1

A', connect points A' and B using a segment, and construct the intersection point of segment A'B and the bottom riverbank. Then it was easy to complete the rest of the steps of the construction. Fred had difficulty understanding the process. I arranged the interview session so that Lisa and Fred worked together as a group. Lisa was happy to answer questions that Fred asked. Both subjects completed the construction of the shortest path - in other words, made a thoughtful conjecture.

(In order to save space by not introducing another figure, let's now consider path AMNB in Figure 1 to be the constructed shortest path.) To verify whether the shortest path was constructed correctly, both subjects created an arbitrary path APQB where Q was a free point on riverbank k and segment PQ represented the bridge (see Figure 1). By continuously dragging point Q and comparing the length of path APQB with that of path AMNB, both subjects observed that path APQB was always longer than path AMNB. Therefore, AMNB was indeed the shortest path.

Since verification itself is not a proof, the problem was not solved yet. Lisa continued her GSP exploration to construct a proof. She began dragging different points around to see how it would affect the distance of the paths, hoping that she would find a clue for proving the conjecture. As she was doing this, she came across exactly what she needed. She found that if she dragged one of the riverbanks close enough to the other so as to make the river width approach 0, a triangle was formed with sides AP, PB, and AB. This meant that when the river width was 0, the constructed path became side AB, and the arbitrary path became sides AP and PB. By the Triangle Inequality Theorem,  $AB < AP + PB$ , confirming that AMNB is the shortest path. Since the river did have a width, the situation was different. However, the only difference was the river width, and the width was included in both paths. When the river width was subtracted from both paths, the situation would be similar to that when the river width

was 0. To remove the river width from both paths, the only thing needed to do was to translate segment AM by vector XX' (see Figure 1). After the translation, the parallel segments AM and NB would become one segment, and the Triangle Inequality Theorem would be used to complete the proof.

### **An Excellent Teaching and Learning Tool That Can Enhance Students' Mathematical Reasoning and Proof Abilities**

GSP has been widely used by teachers, mathematics educators, and students at both school and college levels as an effective teaching and learning tool. However, most of the people use GSP dynamics to help discover properties and relationships, make and test conjectures, and construct geometric objects. In this study, I not only emphasized these aspects of the use of GSP, but also went one step further. I also emphasized that after conjectures were made and tested, the subjects continued GSP explorations to come up with insight for reasoning and proofs. By analyzing the data that I collected in the study, my finding supported that of Battista & Clements (1995) - Sketchpad explorations can not only encourage students to make conjectures, they can foster insight for constructing proofs.

A good example of this aspect has been seen in the Shortest Path problem: Dragging one of the riverbanks close enough to the other and observing the resulting situation fostered insight for proof. Another example in which GSP helped the subjects both make and prove their conjecture was the problem solving process below:

ABC is an arbitrary triangle. Points D, E, and F are respectively on sides BC, CA, and AB.  $BD = (1/3)BC$ ,  $CE = (1/3)CA$ , and  $AF = (1/3)AB$ . PQR is formed by the construction of line segments AD, BE, and CF. What is the relationship between PQR and ABC? (see Figure 2)

When asked to make an initial conjecture, Lisa observed the figure for a while, and then said, "If you ask for the area relationship, it's  $1/3$ , ... no,  $1/9$ , ... no, I am not sure. Less than  $1/3$ ." Fred chose  $1/9$  without being sure either. Through GSP investigations, both subjects found that  $\text{area}(PQR) = (1/7)\text{area}(ABC)$ . Because this problem was quite challenging, the task to prove the finding/conjecture was only assigned to Lisa. She spent quite a while thinking about a proof, but all efforts "led to no where" (her own words). In this case, I asked her to continue her investigation with GSP. Through further work with GSP measurements, she found that  $\text{Area}(BDP) = \text{Area}(CEQ) = \text{Area}(AFR) = (1/3)\text{Area}(PQR) = (1/21)\text{Area}(ABC)$ ;  $\text{Area}(\text{Quadrilateral } DCQP) = \text{Area}(\text{Quadrilateral } EARQ) = \text{Area}(\text{Quadrilateral } FBPR) = (5/3)\text{Area}(PQR) = (5/21)\text{Area}(ABC)$ ;  $BP : PQ : QE = 3 : 3 : 1$ ;  $CQ : QR : RF = 3 : 3 : 1$ ; and  $AR : RP : PD = 3 : 3 : 1$ . She was very interested in these new findings. I suggested that instead of proving the original conjecture directly, she might try to prove a new finding first - for instance, prove the relationship between the smallest triangles (such as BDP) and ABC. She agreed, and continued her active thinking. With minimal help from me (I asked a question: Let  $x$  be the area of BDP and  $y$  be the area of CEP. What are the areas of DCP and EAP?), she finally came up with a proof similar to the one shown in Figure 2:

Let  $x$  be  $\text{Area}(\triangle BDP)$ , then  $\text{Area}(\triangle CDP) = 2x$   
 (because of same height and double base);  
 Let  $y$  be  $\text{Area}(\triangle CEP)$ , then  $\text{Area}(\triangle AEP) = 2y$   
 (same reason). Hence, we have  
 $x + 2x + y = \text{Area}(\triangle BCE) = (1/3)\text{Area}(\triangle ABC) \dots (1)$   
 $2x + y + 2y = \text{Area}(\triangle ADC) = (2/3)\text{Area}(\triangle ABC) \dots (2)$   
 By simple calculations on (1) and (2), we have  
 $x = (1/21)\text{Area}(\triangle ABC)$ . Using similar method,  
 we can get  $\text{Area}(\triangle CEQ) = x = (1/21)\text{Area}(\triangle ABC)$ ,  
 and  $\text{Area}(\triangle AFR) = x = (1/21)\text{Area}(\triangle ABC)$ .  
 Therefore,  $\text{Area}(\triangle PQR) = \text{Area}(\triangle ADC) - \text{Area}(\triangle ARC)$   
 $- \text{Area}(\text{Quadrilateral } DCQP) = (2/3)\text{Area}(\triangle ABC) -$   
 $[\text{Area}(\triangle AFC) - x] - [\text{Area}(\triangle BCE) - x - x] =$   
 $(2/3)\text{Area}(\triangle ABC) - [(1/3)\text{Area}(\triangle ABC) - x] =$   
 $- [(1/3)\text{Area}(\triangle ABC) - 2x] = x + 2x = 3x$   
 $= 3 * (1/21)\text{Area}(\triangle ABC) = (1/7)\text{Area}(\triangle ABC)$ .

Figure 2

She deeply felt that GSP can foster insight for constructing proofs and hence is an excellent teaching and learning tool that can enhance students' mathematical reasoning and proof abilities.

### Different Roles in Helping Students at Different Levels of Geometric Thinking

Research has demonstrated the effectiveness of using GSP in geometry teaching and learning (Dixon, 1997; Choi-koh, 1999). Based on the data collected in this study, I found that GSP plays different roles in helping students at different levels of geometric thinking. The following problem and the subjects' exploration processes provide an example.

**STREET PARKING.** You are on the planning commission for Algebraville, and plans are being made for the downtown shopping district revitalization. The streets are 60 feet wide, and an allowance must be made for both on-street parking and two-way traffic. Fifteen feet of roadway is needed for each lane of traffic. Parking spaces are to be 16 feet long and 10 feet wide, including the lines. Your job is to determine which method of parking – parallel or angle – will allow the most room for the parking of cars and still allow a two-way traffic flow. (You may design parking for one city block (0.1 mile) and use that design for the entire shopping district.)

Both Lisa and Fred gave the same initial conjecture: Angle parking would allow more cars to be parked than parallel parking. Then they began their investigations.

Lisa used paper and pencil to draw diagrams to help thinking. She quickly determined how many cars could be parked in one city block in the parallel parking situation by saying, "The length of the block (528 ft) would be divided by 16 ft, the length of each parking space. This would allow  $528/16 = 33$  parking spaces on each side of the street, giving a total of 66 available parking spaces."

For angle parking, Lisa's investigation process was not so smooth as that for parallel parking. Her diagram is shown in Figure 3. She stated, "Using the Pythagorean Theorem to find  $x$ , we get  $x = \sqrt{16^2 - 15^2} = \sqrt{31} \approx 5.567$  (feet). Now we are left with  $528 - 5.567 = 522.433$  (feet). If we divide this length by the width of the parking space,  $522.433/10 = 52.24$  (feet). Then, *at most* 52 cars would be able to park on each side of the road. Thus, giving 104 available parking spaces."

Figure 3

Figure 4

Figure 5

While indicating that it was good for her to understand the length of the curb space (10 ft in her thinking) was the key to determine how many cars could be parked, I had the following dialogue with her (I stands for the investigator and L stands for Lisa):

I: If a car is exactly 16 feet long and 10 feet wide, can the car be parked in your parking space? (I drew a rectangle on paper to represent a car.)

L: (after thinking for a while) No. The parking space is too small in comparison to the car.

I: What does this tell you?

L: My drawing is wrong.

I: Do you still think angle parking is better?

L: I don't know yet. Need more work.

I: How will you correct the mistake in your diagram?

L: The rectangle should be inside the parking space. (She immediately drew a new diagram shown in Figure 4.)

Even though the new diagram was far from accurate in terms of ratios between segments, the structure was correct. Lisa continued active thinking, and in about ten minutes, she came up with a system of two equations shown in Figure 5. Solving the system of equations would give the length of the curb space, and then the number of cars that could be parked would be easily calculated.

Lisa did not stop at this point, but instead constructed the drawings shown in Figures 4 and 5 in GSP and used GSP measurements and calculations to verify the solution she had obtained. This became her habit later – using GSP as a tool to verify her work after she had developed mathematical solutions or formal proofs.

Fred experienced a much more difficult time in formulating a mathematical solution for the angle-parking situation although he also correctly calculated the number of cars that could be parked in the parallel parking situation. In order to help Fred, I opened a pre-constructed GSP sketch for him (Figure 6).

Below is the dialogue between Fred and me:

I: Look at the current position of the car parking. Is this situation OK?

F: No. It blocks the traffic.

I: How will you change the situation so that the parking is acceptable with the regulations?

F: (Looked at the sketch seriously, and then dragged the point "Drag" down until the yellow rectangle only "touches" the traffic lane [see Figure 7].)

I: What do you observe?

Figure 6

Figure 7

F: (Thought for quite a while.) Now the traffic flows, but space is wasted a lot.

I: Did you see the numerical values displayed on the left-hand side?

F: Yes. Now the curb space is very long. Only 18 cars can be parked on one side of the road.

I: What is your conclusion?

F: Parallel parking is a better choice.

It seems that without GSP as an investigation tool, it would have been difficult for Fred to come up with the more thoughtful conjecture that parallel parking was a better choice. More help was provided to Fred when he tried to explain the new conjecture. This was not the case for Lisa. Sufficient GSP experience had helped her achieve a thinking level at which she was able to make thoughtful conjectures and even develop formal solutions or proofs (for many problems) with or without using GSP. In this case, GSP was more a verification tool than an investigation tool for her.

### **Improvement of the Subjects' van Hiele Levels of Geometric Thinking**

At the beginning of the study, it was found via the pre-test that Lisa was able to perceive relationships between properties and understand logical implications and class inclusions. She was able to do some simple proofs using a two-column format, but not beyond that. For instance, she constantly used the Triangle Angle Sum Theorem, but did not know how to prove it. Therefore she was considered to be at van Hiele level 3 of geometric thinking. During the ten-week teaching interviews, she gradually progressed to level 4 at which she was able to self-initiate efforts to reason deductively and construct proofs. For the ten proof-oriented questions or problems in the post-test, Lisa correctly completed eight and partially completed two. The two problems that Lisa only partially completed had a certain degree of difficulty, and it was understandable that she was not able to complete them in limited time. Among the eight problems that she correctly completed, one was: *Two circles intersect at Points A and B. A line passing through A intersects the two circles respectively at C and D. A line passing through B intersects the two circles respectively at E and F. What is the relationship between lines (or segments) CE and DF? Can you prove your conjecture?* Lisa quickly conjectured that line segments CE and DF were parallel through visual observation. She also quickly verified her conjecture by dragging points on the circles to see if the lines would still look parallel, and they did. To prove the conjecture, however, was a challenge. It required the understanding of the Cyclic Quadrilateral Theorem and the theorems to prove two lines are parallel. Furthermore, the key for developing a proof was the flexibility to create cyclic quadrilaterals that did not exist explicitly in the first place. After active thinking, Lisa showed this flexibility by constructing segment AB to form two cyclic quadrilaterals. Then the rest of the proof became straightforward. It was evident that Lisa had progressed to solid van Hiele level 4 of geometric thinking.

Fred also demonstrated the development of his geometric thinking during the ten-week teaching interviews. His performance in the post-test showed that he had progressed from his original level (van Hiele level 2) to a thinking level at which he was able to identify relationships and categorize figures in a hierarchical order (van Hiele level 3). For example, he knew that a square is a rectangle, but a rectangle is not necessarily a square. Similarly, a rhombus is a parallelogram, but not vice-versa. He recognized that the set of all rectangles is bigger than the set of all squares. Furthermore, he was able to understand and sometimes even present logical arguments. For example, Fred had difficulty to do the deductive proof in the parking problem. However, when he discussed the problem with Lisa, he was able to understand Lisa's reasoning. After the discussion, he was able to explain why the parallel parking was better on his own.

### **Changes in the Subjects' Conceptions of Mathematics and Mathematics Teaching**

#### **Teaching**

The subjects' conceptions of mathematics and mathematics teaching significantly changed as a result of their experience in the interview sessions.

The interactive, dynamic, and innovative features of GSP allow students who might not be interested in mathematics to become active participants in exploring mathematics. Previously, teachers lectured and were the ones doing all the work on the board. Students had little determination so that they became unproductive and uninterested in the subject matter. However, with GSP, students now have the opportunity to get involved in the teaching and learning processes by making, verifying, and proving their own conjectures. Before participating in the teaching interviews, Fred didn't like geometry, and fell asleep in geometry classrooms. Now, he enjoys geometric learning. He indicated, "One of the reasons that I am so interested in this class is because we use computers. I am like a little kid and my attention is easily caught by the use of a computer."

Before the teaching interviews, Lisa agreed to the following statement, "To understand mathematics, students must solve many problems following examples provided." She explained that this was the way she had been taught mathematics her entire life. The teacher provides examples and the students imitate the procedures. She wouldn't know any other way of learning and teaching mathematics. However, after participating in the teaching interviews, she realized that students can understand mathematics, perhaps even better if they discover/explore solutions to mathematics problems themselves than if they simply mimic the teacher's examples. She indicated that, in the MAE 3651 class, the instructor hardly provided examples for students to follow. Rather, the students were given problem situations and had to find solutions themselves. This teaching method got all students involved and interested. In the process of finding a solution, students learned why the solution worked. Thus, they understood the related mathematics without following a given example.

Before the teaching interviews, Lisa agreed to the statement, “Students should have opportunities to experience manipulating materials in the mathematics classroom before teachers introduce mathematics vocabulary,” but did not think it was *necessary*. She stated, “Yes, students should have the opportunity to use manipulatives now and then, but it is not essential. Additionally, I hesitated to say that I strongly agree because I also found it a little difficult to imagine that students could work with materials without knowing the terms of what it was they were looking for.” However, after participating in the teaching interviews, she realized that knowing the vocabulary is not critical when trying to find a solution or an explanation/proof. What is important is the process of problem solving and conceptual understanding.

### **Implications for Preparing Mathematics Teachers**

This study was conducted within the course “Learning Mathematics with Technology” (MAE 3651). The results of the study seem to suggest that a course like MAE 3651 be necessary for preservice mathematics teachers (at least currently). First, preservice teachers should understand the mathematics they will be teaching at and beyond the level expected of their future students (MAA, 1991). To the study of geometry, judging, constructing, and communicating mathematically appropriate arguments remain central (NCTM, 2000). Therefore, preservice teachers should be provided with opportunities to develop their mathematical reasoning and proof abilities. In terms of the van Hiele model of geometric thinking, they should reach at least level 4 (ideally level 5). A course like MAE 3651 can assist them towards that goal. Second, geometry has always been a neglected area in mathematics education (NCTM, 1991). A majority of the preservice teachers did not get chances to seriously learn geometry in high school where the focus was on procedures and finding answers. Students like Lisa have stronger geometric background than most of their peers. Even so, however, they lack the necessary knowledge and skills in developing proofs. Students like Fred lack both geometric intuition and conceptual understanding. Therefore, most of the preservice teachers are not ready for *College Geometry*, which is a required course of most teacher preparation programs in the nation. In that course, formal proofs are a norm and students reason about mathematical systems. Students at a thinking level lower than van Hiele level 4 are not able to make sense of the formal aspects of deduction. This explains why it was difficult for most preservice teachers to even pass that course. With a course like MAE 3651 as its preparation, the situation can be fundamentally improved. Third, preservice teachers often have little exposure to the type of investigative mathematics that lies at the heart of NCTM Standards (2000). In a course like MAE 3651, they are required to learn mathematics through hands-on and minds-on investigations and explorations. Finally, dynamic geometry in general, and GSP in particular, is one of the best examples of technology that can be used to support innovative learning and teaching of mathematics. Teacher preparation programs should recognize the need to increase future teachers’ knowledge of geometry, help

them develop their own mathematical power, and expose them to innovative methods of mathematics learning and teaching through the use of dynamic geometry software, especially GSP.

## **ENGAGING TEACHERS IN RESEARCH THROUGH PROBLEM SOLVING AND PROBLEM POSING WITH DYNAMIC GEOMETRY SOFTWARE**

Armando M. Martínez-Cruz  
California State University, Fullerton  
amartinez-cruz@fullerton.edu

José N. Contreras  
The University of Southern Mississippi  
jose.Contreras@usm.edu

The main research objective of this study is to engage future and current secondary mathematics teachers in mathematical research by conjecturing a geometry result using dynamic software. A college geometry course for future and current secondary mathematics teachers taught in the spring was selected as the setting of this study. We report here the effects of incorporating problem solving and problem posing activities in this course. Students were asked, as a final project, to find a “new” geometry theorem (i.e., a result that they did not know or was not covered in class) using dynamic geometry software. A total of 46 conjectures were produced. Additionally, students were asked to react to this activity in a 1-2 paragraph. Although students felt initially intimidated by the assignment, conjectures produced suggest, on one side, that future and current mathematics teachers can generate interesting and significant geometry conjectures, and on the other side, that all the students found the assignment engaging, interesting and satisfying. The data reported correspond to two sections of this course (2001 and 2002).

### **Objectives or Purposes**

This study is part of an ongoing project that seeks to involve future and current secondary mathematics teachers in mathematical research. This paper reports the effects of incorporating problem solving and problem posing activities in a college geometry course for secondary mathematics teachers. First, we wanted to investigate students’ abilities to pose problems using dynamic software with a semester-long exposition to problem solving and problem posing activities. Second, we wanted to study students’ affective responses to investigating a mathematical situation without a specific task. To this end, teachers in a college geometry course were asked to find an “original” conjecture in geometry with the aid of dynamic geometry software. Original was defined as a result that had not been covered in class or they had not seen in a book. Students also wrote a 1-2 paragraph about how they felt about this task.

### **Perspective(s) or Theoretical Framework**

A central goal in mathematics education (NCTM, 2000) is that students become mathematical problem solvers. Teachers play an essential role in this enterprise (NCTM, 2000). Teachers are expected to model and emphasize “aspects of problem solving, including formulating and posing problems, solving problems using different strategies, verifying and interpreting results, and generalizing solutions” (NCTM, 1991, p. 95).

Posing problem or problem formulation (Silver, 1994) is increasingly receiving attention from both a curricular and pedagogical perspective (NCTM, 2000). For instance the *Principles and Standards for School Mathematics* (NCTM, 2000) states that “students should have frequent opportunities to formulate, grapple with, and solve complex problems that require a significant amount of effort and should then be encouraged to reflect on their thinking” (p. 52).

Unfortunately teachers lack abilities to pose problems. For instance, the authors describe that future teachers both elementary (2000, 2001) and secondary (1999) teachers have limited abilities to pose mathematical problems. In the particular case of secondary mathematics teachers, the authors (1999) identify the need of future teachers to learn how to pose problems in systematic ways. A systematic approach to pose problem has been built using Contreras (1998) and Moses, Bjork & Goldenberg (1990). This systematic approach to pose problems is referred as a problem-posing model and consists of seven strategies: Variation of unknowns, variations of knowns or givens, variation of restrictions, reversing knowns and unknowns (converse-type problems), generalizing, thinking of patterns, and proving.

“The college geometry course is especially important for prospective secondary mathematics teachers. [...] Not only does the college geometry course need to lay a strong foundation for the content they will eventually teach, but it is also one of the few courses that might develop the preservice teachers’ ability to create and present proofs” (Gover & Connor, 2000, p. 48). Furthermore, we propose that the college geometry course supported with interactive geometry software provides an environment in which secondary mathematics teaching majors can engage in problem posing as well.

### **Methods or Modes of Inquiry**

The *Principles and Standards for School Mathematics* (NCTM, 2000) recommends that students should “examine patterns and structures to detect regularities [and] formulate generalizations and conjectures about observed regularities” (p. 262). Geometry, in particular, offers many opportunities for students to examine visual regularities and hidden patterns. Interactive geometry software such as the Geometer’s Sketchpad (Jackiw, 1995) facilitates searching for geometric patterns and the formulation of conjectures because it can construct geometric configurations with precision. It also enables the learner to test the observed patterns and the formulated conjectures or generalizations by dynamically and quickly generating a large number of instances.

A college geometry class taught by one of the authors during the spring was chosen as the setting for this study. The study spans over a two-year period and includes two section of the college geometry course, one section in Spring 2001 and one section in Spring 2002. The class is an undergraduate course but it is also open to graduate students. During the spring 2001, eight males and 13 females completed the course. There were 12 undergraduate students, six graduate students and three post-degree students. During the spring 2002, 13 females and 12 males completed

the course. There were 19 undergraduate students, two graduate students, and four post-degree students.

Students were asked to produce an original conjecture as a final project for the class. This assignment was included in the syllabus and students were notified of it the first day of class. Students were also told that they were supposed to “discover” the conjecture with the aid of geometry software. They were told as well that the class would provide instruction on the use of the software and ample opportunities to solve and pose problems with its aid. Since the authors did not know the level of difficulty of the conjectures that the students would pose, to release some of the stress from the task, students were asked not to prove the result, but at least to try to prove it. Also, students were told that an original result meant a result that had not been covered in class or that they had not seen in a book.

The class met twice every week, Mondays and Wednesdays from 4-5:15pm. All the meetings took place in the computer lab. Hence each student had access to a computer. We used Geometer's Sketchpad, GSP (Jackiw, 1995) version 3 during Spring 2001 and version 4 during spring 2002. Some students purchased the student version of this software.

The second author was invited to illustrate the use of a framework to pose problems (Contreras, 1998) in systematic ways during the second week of Spring 2001. The presentation centered around geometry tasks aided with dynamic geometry software (GSP; Jackiw, 1995). This class then continued covering the material and emphasizing the application of the framework when relevant. Towards the 11<sup>th</sup> week of classes the instructor provided students with a list of suggestions for problems. The purpose of this list was for the students to formulate or pose new problems by varying or modifying the conditions of the problem. In contrast, students in the spring 2002 did not meet the second author or received a list of problems. However, the instructor invited a former student, Ron, to present his conjecture during class. Ron found a conjecture working on the diagram associated with the Pythagorean Theorem (McAllister, Martínez-Cruz & Gannon, in preparation).

Also, as the class in spring 2001, the spring 2002 section experienced the application of the problem-posing framework when relevant. To illustrate, one of the problems in homework was the following: “Given a square, construct the centroid of each of the triangles formed with three consecutive vertices of the square. Next join pairs of consecutive centroids counterclockwise. What kind of quadrilateral is formed? Prove it!” (See Figure 1).

After, the homework was graded and the problem was discussed in class, the instructor discussed the possibility of generating new prob-

Figure 1

lems from this problem. In particular, we looked at varying the knowns, in this case a square—which is a regular quadrilateral. So we looked at the situation when we have other quadrilaterals such as a rectangle or a parallelogram. We constructed the newly generated situation for the rectangle with GSP and discussed in more detail than when working with a parallelogram. We also suggested how to prove the result observed. No further comment was done on what other figures to try, however it was underlined how we had generated another problem by varying a known, and conjectured a result with the aid of geometry dynamic software.

### Data Sources or Evidence

Students presented their projects in class during the last two weeks of each semester. A total of twenty-one projects were collected in Spring 2001, and twenty-five projects in Spring 2002. Some projects were presented as conjectures and others as problems. We provide three samples of students' work from Spring 2001. All three contain a sketch. We have included only the sketches for the last two projects. This presentation does not imply any ranking.

- (1) Conjecture: Given a golden rectangle, the sum of the areas of the infinite number of circles that can be made using the sides of the inscribed golden rectangles as radii is to the largest circles as the longer side of the original rectangle is to it's (sic) shorter side.
- (2) Theorem: In any ellipse, the triangle inscribed in a semi-ellipse with the base as the minor axis is acute. ( $<90^\circ$ ). Likewise, the triangle inscribed in a semi-ellipse with the base as the major axis is obtuse. ( $>90^\circ$ ). See Figure 2.
- (3) Properties of  $\triangle KEN$  in comparison with  $\triangle USC$ .  $\triangle KEN$  is constructed by taking any interior point "P" of  $\triangle USC$ , connecting point "P" with each of the vertices to make 3  $\triangle$ 's and then constructing the centroids of each of the 3  $\triangle$ 's to form  $\triangle KEN$ .

Theorem: The triangle ( $\triangle KEN$ ) formed by connecting the three centroids of three triangles formed from an interior point of a given triangle ( $\triangle CSU$ ) are similar. In other words,  $\triangle KEN \sim \triangle CSU$ . See Figure 3.

Figure 2

Figure 3

Additionally, as a last assignment, students were asked to “write 1-2 paragraphs on how they felt about the assignment ‘discover a new theorem’ using GSP”. During the conference we will add to the discussion the projects from Spring 2002.

### **Results and/or Conclusions/Points of View**

The results discussed in this section refer to data collected during Spring 2001. During the conference we will combine and discuss the data collected in both sections.

### **Students’ Abilities to Pose Problems Using Dynamic Software**

We used the same framework (Contreras, 1998) to analyze the problems. During the presentation, we will illustrate how this was done. A first analysis of the 21 problems students proposed shows that the most common strategies to pose problems were: (a) variations of knowns or givens, variation of restrictions, and generalizing. For instance, the second problem mentioned above came out of the Theorem “An angle inscribed in a semicircle is right.” The student posed the problem for an ellipse (instead of a circle) and varied the situation accordingly (in the case of a circle, it is necessary to use a diameter, but in the case of the ellipse, the student worked with major and minor axis).

Unfortunately, this framework does not address the quality of the problem. In other words, what constitutes an interesting, nice, or beautiful problem? Certainly, not all the problems the students came out with have all of these features. However, the authors agree that each of the three problems presented above are interesting, nice and beautiful to some extent. When we bring into the discussion these qualities, it is hard to assess them and separate them from students’ affective responses to the assignment. This is addressed below and adds information to the students’ abilities to pose problems.

### **Students’ Affective Responses to Investigating a Mathematics Situation Without a Specific Task**

All students (in both sections) mentioned that the activity had been “enjoyable” with the majority at the beginning of the semester feeling it would be “impossible” to complete. As one student said “I never figured I would find anything and if I did we would already have learned about it in class.”

Some students mentioned that the task integrated geometry patterns, exploration and learning. The use of the software had facilitated “the exploration of geometric relationships from the investigate point of view,” and “exploration is...one of the best ways to learn something. When you explore, you seem to better understand that which you have ‘discovered’, and you learn more along the way than you with most other activities”.

The disappointment of not finding a result, maybe right away, emerged in one comment: “The only disappointment (sic), however, was encountered when I would

explore some hypothesis I had expecting to find some geometric constant. Most of the time, to my dissapointment (sic), I could not find any truths.” However, another student pointed to this situation in a constructive way. “I thought a particular relation might hold for all cases, but I was able to find a counterexample without too much effort.”

Several students mentioned about the ownership of the material through discovery: “Discovering something new, even if it is only new to yourself, is wonderful”. Finally, several students mentioned about how the task made them “feel like they were actually contributing to the field of mathematics”.

One of the situations that we noticed after students had observed a pattern was the quick tendency to claim the conjecture as a fact. We overemphasized that to be fact the students needed to find a proof of the conjecture and stressed the importance of writing their conjectures starting with the phrase “It seems that ....” However, still during the presentations, several students started their presentation as if the result were a fact. So, it seems that more can be done for the importance and need of proofs as opposed to a large number of evidence.

We believe that we instilled in some students the idea of being curious in mathematics. This is important since we believe it gets to the core of the teacher-researcher issue. To what extent it is an open question. However, we are pleased to report that the first author worked with three students on independent studies during Fall 2001 to pursue and deepen the investigation of their conjectures. A presentation at MAA (Martínez-Cruz & Ohgi, 2001) addressed the work of one of these students.

### Relationship to Goals of PME-NA

This study builds on previous research reported at PME-NA meetings. In particular, it seeks a better understanding of the psychological aspects of teaching and learning geometry and the implications thereof.

# **STUDENTS' DEVELOPMENT OF THREE-DIMENSIONAL VISUALIZATION IN THE GEOMETER'S SKETCHPAD ENVIRONMENT**

Edwin McClintock, Zhonghong Jiang, & Raquel July  
Florida International University  
mcclinto@fiu.edu

This article reports a series of four studies carried out over a period of four years. These related studies were clinical and qualitative, as they investigated middle and high school students' development of geometric thought, particularly as it related to three-dimensional visualization. The studies were carried out in the constructivist pedagogical style. The Geometer's Sketchpad was instrumental in all of these studies and it was this environment in which the subjects learned to increasingly develop their visualization abilities as they solved challenging geometry problems. Platonic solids, Archimedean solids, other geometric solids, and the mathematical relationships related to these solids were the objects of study. Students' van Hiele levels of geometric thinking were monitored as they constructed dynamic GSP representations of these solids to conduct geometric investigations. A fundamental finding was that GSP provided opportunities to have a distinct positive affect on students' learning of three-dimensional geometry.

According to the NCTM Standards documents (1989, 2000), in high school geometry, all students should have opportunities to visualize and work with three-dimensional figures in order to develop spatial skills fundamental to everyday life and to many careers. Geometry instruction should focus increased attention on the analysis of three-dimensional figures. It should focus on the continued development of students' skills in visualization and pictorial representation of three-dimensional figures.

Research (Ben-Chaim, Lappan, & Hoaung, 1988) suggests that spatial strategies can be taught successfully to middle and high school students. Appropriate use of three-dimensional representation and computer software is of particular value in development of three-dimensional visualization. Particularly, the Geometer's Sketchpad (GSP) developed by Jackiw (1995), a dynamic geometry construction and exploration tool has become widely introduced into classrooms of mathematics and science, especially of geometry. Its effects on different fields have been topics of research. Dixon (1997) investigated its effects on eighth grade students' spatial visualization. Her research results suggest that the GSP instructional environment was more effective than the traditional instructional environment at improving students' two-dimensional visualization, but was not more effective than the traditional instructional environment at improving students' three-dimensional visualization.

Bishop (1983), in describing his previous works in spatial thinking, presents two different but similar spatial abilities:

- 1) The ability for interpreting figural information (IFI). This ability involves understanding the visual representations and spatial vocabulary used in

geometric work, graphs, charts, and diagrams of all types. Mathematics abounds with such forms and IFI concerns the reading, understanding, and interpreting of such information. It is an ability of content and of context, and relates particularly to the form of the stimulus material. 2) The ability for visual processing (VP). This ability involves visualization and the translation of abstract relationships and nonfigural information into visual terms. It also includes the manipulation and transformation of visual representations and visual imagery. It is an ability of process, and does not relate to the form of stimulus material presented. (p. 185)

According to Bishop, these definitions refine and extend the definitions given by McGee (1979). IFI extends the spatial orientation of McGee to include geometric and graphical conventions and refines it by emphasizing "the interpretation demanded by those representations" (p. 185). VP as well is refined and extended by emphasizing "the process aspect rather than the form of the stimulus" (p. 185). Thus, three-dimensional spatial ability includes both the ability of interpreting figural information in the context of three-dimensional objects and the ability for visual processing of these objects.

### **The Purpose of the Research**

The purpose of the research was to investigate the effects of the GSP dynamic instructional environment on middle and high school students' three-dimensional visualization. The following questions were investigated in the studies:

- 1) What role can the GSP dynamic instructional environment play in the development of students' three-dimensional visualization? Is there evidence to indicate improvement in students' three-dimensional spatial ability when GSP is used to teach three-dimensional geometry?
- 2) What role can the GSP dynamic instructional environment play in the development of students' geometric thinking as defined by the van Hiele theory? Is there evidence to indicate improvement in students' geometric thinking when GSP is used to teach three-dimensional geometry?

### **Significance**

This article describes a series of research studies that focus on the use of GSP in improving students' three-dimensional visualization, one of the important aspects in developing a reform-oriented geometry curriculum. More and more educators believe that the use of technology can effectively facilitate the teaching and learning of mathematics. The NCTM Standards documents (1989, 2000) emphasize the effective use of technology as one of the main feature of the reform curriculum. However, technology-related research on students' three-dimensional visualization is very limited. Increasingly, mathematics educators and teachers need quality technology-related research

to “inform us of the conceptual linkages among new and old ideas and orientations and how these might be influenced by various instructional strategies and materials” (Kaput & Thompson, 1994, p. 680). It is this concern that the research studies took into consideration. They explored evidence supporting the belief that students could benefit from the use of technology. The research results will contribute to our current limited understanding of the students’ development of three-dimensional visualization and geometric thought within a technology-rich environment.

### **Conceptual Framework**

The conceptual framework of the research was the constructivist perspective that knowledge is not passively received from the teacher but actively constructed by the learners themselves, the van Hiele model of students’ geometric thought, and the previous research on three-dimensional visualization. According to van Hiele (1986), students progress in geometric thinking through taxonomy of levels, and progress from one level to the next higher level is dependent on the nature of the instruction provided to students. The five van Hiele levels are Level 1: Visual (figures recognized by appearance alone), Level 2: Analysis of Properties (properties perceived, but isolated and unrelated), Level 3: Ordering/Hierarchy (relationships, implications, & class inclusions), Level 4: Deduction/Proof (deduction is meaningful, can construct proofs), and Level 5: Rigor (formal aspects of deductions, symbols manipulated). Within this framework, the van Hiele model was examined in light of the use of technology. van Hiele’s research and particularly the view of levels of thought and the lack of communication among levels may need to be updated for an educational system in which technology is an integral component.

### **Design and Procedure**

Constructivist teaching experiments were used for these investigations. Over a four-year period, twenty-four students were provided increasingly more challenging geometry units with GSP as a central feature throughout. The class as a whole was engaged in problem solving in geometry, which included GSP constructions, investigations, and dynamic experimentation. However, since we were interested in the students’ detailed changes and growth in their thinking processes, we focused on looking at individuals and used a clinical approach to assess students’ growth in geometric thought.

The class of twenty-four students was a part of the Partnership Academic Community (PAC) program, a collaboration between Florida International University and Miami-Dade County Public Schools. This program aims to help at-risk minority students of metro Miami area to improve their academic and behavioral achievement by placing them in a reform-oriented, technology-rich learning environment. The PAC students are from three middle schools and a high school of Miami-Dade School District. Most of them are African-Americans and Hispanics and from lower socio-

economic families. The subjects involved in the clinical studies were selected for their willingness and also for their different mathematics thinking levels.

The teaching experiments progressed through four phases, which are summarized in the following two tables:

A part of the progression from study to study is the extent to which the envelope is being pushed. For example, in studies dating back to 1997, the inquiry was on tasks directly related to the studies of the van Hiele, of basically plane geometry concepts with an easy entry into solid geometry concepts such as perspective views of solid figures. In more recent studies, the investigation of plane geometric concepts embedded in three-dimensional objects was undertaken. Another dimension of growth in inquiry was providing subjects with physical geometric objects and requesting their construction in GSP as dynamic representations on which transformations such as rotations and translations and specific components such as cross sections could be investigated.

The exploration activities/problems used in the studies were devised in ways that (a) the subjects were required to use hands-on explorations with GSP to learn new geometric ideas; (b) they were required to make conjectures based on their explorations; (c) they were required to make meaningful explanations for whatever conjectures they made; and (d) they were asked to look back to check if they had reached a complete understanding. Our goal was to use these activities to help each subject develop three-dimensional visualization and make orderly progress in the movement from the van Hiele level he or she was currently at to a higher level.

### **Data Collection**

Detailed notes were taken when observing the teaching sessions in all four phases. Some of the sessions and all teaching interviews were videotaped. Significant parts of the videotapes were transcribed. The computer files on the disks, and the written tasks completed by the students throughout the four phases, were also collected.

### **Data Analysis**

A constant comparative approach was used to analyze the collected data. The constant comparative method of qualitative data analysis (Glaser & Strauss, 1967; Grove, 1988) serves as a model demonstrating how systematic analysis can improve the validity of a qualitative research study. Constant comparison involves analyzing and interpreting data during and after data collection. Using this method, the transcripts and other data were analyzed during teaching sessions and after all sessions were completed. These analyses took the form of editing a set of transcripts and other data with commentaries. The commentaries depicted the story lines of the corresponding students' progression through the sessions.

### **Results**

The results of the research suggest that GSP and the associated activities were effective in helping the students develop three-dimensional visualization and achieve conceptual understanding of geometry content.

**GSP helped the students generate and sustain insight and enthusiasm in learning three-dimensional geometry.**

Starting in grade 7, the subjects of these studies had positive attitudes toward the use of GSP. They found it interesting and dynamic. They found it a friendly environment in which they could play around and experiment. Using GSP to learn geometry in an experimental fashion has contributed to the subjects' enthusiasm for geometric exploration. In some sense, GSP was not considered a geometric environment so much as an artistic and creative environment by these subjects.

Periodically, the students in these studies were asked their views of using computers, particularly their views related to GSP. Consistently, they expressed their continuing enjoyment and valuing of GSP as a tool for learning. The ways that the subjects used GSP changed form over the years. Initially subjects made simple creative uses as they learned the capabilities of GSP. Then they began to make sense of problem situations; for example, making operational the definition of geometric objects (e.g., a dodecahedron). The three-dimensional uses of GSP emerged early (during the 7<sup>th</sup> grade) when they turned to the study of perspective drawing. Problems such as finding a hexagonal cross section of a cube and showing it visually moved the use of GSP to focused challenges.

The dynamic possibilities of GSP emerged during the 8<sup>th</sup> grade year, as students used hints and challenges to do transformations of three-dimensional objects and their cross sections. They expressed the positive attitudes that emerged in the new ways of experiencing the GSP environment. One of our subjects expressed it well, as follows:

I like the ones that move...the animation...it's different from the object just staying still on the screen...It becomes easier because that knowledge from GSP is in your head and your head is working like GSP, so you can think about it, rotate it. GSP helps you really think about it, you use the program in your head, as a screen in your mind so that if you construct a figure...say a perpendicular line, you can see it in the screen (in your mind).

The dynamics held continuing opportunities for geometric exploration far beyond what we had done before, and the subjects were able to create solids that could be transformed. The solids could be rotated, and the cross section slices on it could be translated and rotated as well. Our subjects found these uses of GSP brought new challenges. They realized the implications for a deeper level of study of geometric objects. In the 9<sup>th</sup> and 10<sup>th</sup> grade years, Platonic solids and Archimedean solids became objects of study. The animation of GSP helped students to analyze the structure of these objects in an in-depth way. Some tasks were provided that challenged the subjects of these studies to make sense of the meaning of duality while finding the dual of each Platonic solid. Other tasks challenged our subjects to use slicing planes to create Archimedean solids from given Platonic solids. These tasks brought a new dimension to the GSP exploration. Likewise, tasks that requested our subjects to construct in GSP

an Archimedean solid from the net of such a solid expected higher levels of visualization. Through these types of tasks, our subjects built GSP planar representations of the related polyhedra. The use of these dynamic GSP representations permitted our subjects to study the features of each solid, and for some the result was an understanding of the structure of the solid. However, possibly the greater value of these tasks was that they enticed the subjects into a greater mental involvement in the study of three-dimensional geometry. Their enjoyment of this type of study was a key, we believe, to the development of spatial thinking of our subjects. The evidence that we have, beyond what we could observe the students doing and saying was that about 50% of them reported in post-study surveys the influence that GSP had upon their spatial understanding. Some of the students' comments were:

"I like working on the computer more because it is fun, and GSP helps me to learn geometry but at a higher level of understanding because I have all the visual I need right in front of me."

"I learned a lot about things like the properties of solids, regularity, shapes, and 2-D dynamic constructions. The computers really helped me to see and know these things because sometimes I couldn't visualize these things that were so easily shown on GSP... The GSP program would be a great learning tool to use because the student in order to construct a figure or a shape must take the properties of that shape into consideration."

"GSP helped us look at the objects and shapes from different points of view and in a way that helped record the information into our minds."

Thus the GSP dynamic environment effectively facilitated the affective learning, and the sense of enjoyment and ownership of our subjects. We believe this affective learning indirectly contributes to the development of spatial visualization abilities.

**GSP, by providing immediate feedback, helped students efficiently confirm or correct their conjectures.**

In the teaching experiments, the investigators followed the constructivist approach where the subjects were requested to learn new ideas by exploring given task situations. As the first step of the exploration, the investigator always encouraged the subjects to make initial conjectures. Looking back over the many initial conjectures the subjects made we found that a large portion of those conjectures were incorrect. Making incorrect initial conjectures was not a bad thing, and seemed to be normal in students' learning process. From the constructivist point of view, substantive learning takes place over a long period of time and occurs during periods of confusion and conflict. In the teaching sessions designed for these studies, as soon as the subjects made their initial conjectures, they were allowed (and at the same time they were very eager) to manipulate the GSP dynamic models to check their ideas. The immediate visual feedback provided by these models stimulated the subjects' strong

desire to struggle against and clear their mental confusion and conflict, thus achieving improved understanding. The interview with a subject (Laura) in Phase 3 gives a good example of this aspect.

The interview was designed to compare the GSP dynamic planar representation with a static paper-and-pencil test in facilitating the subject's three-dimensional visualization. Laura was given a two-dimensional figure of a regular icosahedron. The given figure only showed its front elements (vertices, edges, and faces), with its back elements missing (Figure 1). The task was to add all missing elements to complete the figure.

Laura took a pencil-and-paper test first. To add the missing elements, she tried hard to image the spatial structure of a regular icosahedron. Even though she added some elements (e.g., one missing vertex on the upper pentagon cross section and two missing vertices on the lower pentagon cross section) correctly, she was not able to visualize the complete structure of the regular icosahedron. Figure 2 shows her drawing - an apparently incorrect conjecture.

Soon after the paper-and-pencil version of the task, Laura began the GSP test. In this case, she was given a GSP sketch of dynamic planar representation of the regular icosahedron. She rotated the planar representation by dragging the free point (on the small circle) around (see Figure 3). In the course of rotation, she had opportunity to observe the continuous change of images of the icosahedron. In other words, she experienced different orientations of the planar representation of the solid. This effectively enhanced her visualization on the solid. She quickly said, "Oh, my drawing was wrong." To add the missing elements correctly, she continued to drag the free point and moved it around, sometime fast, sometime slowly.

The investigator observed that when the subject rotated the figure, she approximated the positions of the missing elements and checked her approximation by slow-

Figure 1. A figure of an icosahedron with missing elements.

Figure 2. Laura's drawing for the missing elements.

Figure 3. Two specific positions in the course of rotation.

Figure 4. Laura's drawing in the GSP test.

failed based on the limited information that the static planar figure provided. She was only able to develop an incomplete internal representation of the solid. After she finished the GSP test, the investigator had a conversation with her.

I: Look at the picture you drew on your paper-and-pencil test.

L: I know there was something wrong.

ing down her rotation and moving the free point back and forth. In about three minutes, she finished her drawing (See Figure 4). This time, she figured out the positions of all missing vertices accurately and connected all missing edges correctly. The drawing suggests that with the feedback that GSP animation provided, Laura corrected her misconceptions and achieved a better understanding of the spatial structure of the regular icosahedron.

In the paper-and-pencil test Laura was struggling to visualize the complete spatial structure of the object, but she

I: I would like to understand how you drew the picture like this.

L: Well, I was thinking there should be ten faces in the middle.

I: Could you try counting the faces? How would that help?

Then she began to count the faces in the middle. "Here we go. When I counted the faces in the middle, I missed these two triangles," she said, while pointing at the two most "outside" triangular faces (see Figure 2). Thus she was able to clear up her own confusion. The conversation allowed us to see the clear picture of her mental process. At first, she had some understanding of the spatial structure of the object, and so she knew there were five faces in the upper part and ten faces in the middle. In fact, she drew the missing vertices in the upper cross section correctly. However, because of her confused spatial visualization on the static planar figure she was not able to draw the missing vertices in the lower part correctly. In the GSP test, through manipulating the dynamic planar representation of the solid, she reached a better understanding of the structural properties, made progress on the logical connections, and found out what was wrong with her previous drawing. Thus, she developed a more complete mental representation of the solid.

Another example is the following task given to the subjects in the interview sessions in Phase 4. They were requested to produce and study the polyhedron represented by the net shown in Figure 5. Typical misconceptions that arose in this setting included interpreting the adjacent equilateral triangles as a parallelogram. Two of the subjects then concluded that the resulting polyhedron was a rectangular prism, and two concluded that the solid could not be formed. To help the subjects visualize the solid they were studying, they were introduced to a pre-constructed GSP sketch that allowed them to fold the net into a solid and unfold the solid back to the net by clicking the related buttons. This experience allowed the subjects to see that the triangles could fold into different planes (i.e., their conjectures were incorrect) and led them to

Figure 5. Task: Construct the polyhedron that this net represents.

Figure 6. Manuel's GSP construction of the polyhedron from the net.

re-analyze the net. This type of feedback mechanism became a pattern of inquiry that aided visualization. With minimal study, the subjects were able to determine the polyhedron that the net represented. One of the subjects (Manuel) was able to construct a dynamic GSP model of the solid within a few minutes because he was able to visualize the polyhedron. He rotated his GSP model and quickly indicated that this was it. The rotations enabled him to test out this construction and see if it fitted his image. This use of GSP is instructive and provides avenues for constructing meaning.

Along with the subjects' progression in the teaching experiments, we did find the subjects gradually made fewer incorrect conjectures.

**The GSP dynamic environment helped the students concentrate on the logical (rather than visual) properties of three-dimensional objects.**

For a two-dimensional object, if we construct its external representation which preserve all of its logical properties, then the visual properties of the representation are consistent with the logical properties of the geometric object. In this case, students can guess some properties of a geometric object based on the visual properties (using observation and measurement tools) due to the consistency. For a three-dimensional object, however, even though we construct its two-dimensional representation using the perspective approach, the visual properties of the two-dimensional representation are usually not consistent with the logical properties of the geometric object. For example, parallel perspective planar representation maintains some properties of three-dimensional objects such as parallelism and the ratio of collinear segments, but the representation does not keep some other properties of the objects such as the perpendicularity or congruency of segments and angles. Due to the influence of the approaches they applied to exploring two-dimensional objects and the limitation of their logical reasoning ability, students tend to draw conclusions based on the visual properties of the static planar representation rather than the logical properties of the three-dimensional objects. GSP can provide students with dynamic two-dimensional representations of three-dimensional objects, and adding the dynamic dimension can help students overcome the obstacle. That is, by manipulating the dynamic planar representations such as rotating them, students are able to induce logical properties of the geometric objects, because the visual properties of the external representations move to the background. In addition, students can control the motion. In this way the GSP dynamic instructional environment is valuable to develop students' internal representation (mental image) of three-dimensional objects.

As an illustration of how GSP dynamics helped our young subjects user logical properties to make and verify conjectures, we offer the following example - the problem situation shown in Figure 7, as it was presented to a subject (Mary) in Phase 3:

The problem asked for a comparison between the two segments highlighted in the two dimensional-representation of a regular icosahedron. In the paper-and-pencil test that was given to her first, Mary thought that segment US was not congruent to but

longer than segment RT. She was led to a faulty inference because the static view was interpreted so that RT was seen as an edge of the icosahedron. Her explanation was that segment US went all the way across the three-dimensional figure (solid) but segment RT went by the edge of the solid. The explanation revealed that her incorrect judgement came from the wrong visualization of the planar representation of the solid. Mary was at a higher thinking level than many students in her class, but she still visualized RT as an edge of the figure before she was able to relate the visual and logical structures. We can see from here the sharp difference between the static two-dimensional representation of a solid and the solid itself, and the strong influence of the difference on how students interpret the visual.

After Mary completed the paper-and-pencil test, the investigator showed her a GSP dynamic two-dimensional representation displayed in Figure 8. Mary clicked the Rotation button, and found immediately a quite different visualization from that in the paper-and-pencil situation. In order to see all possible orientations given by the dynamic representation, she chose to drag the free point on the small circle to observe the rotation in a controlled speed. The feedback that the dynamic

The following figure is the planar representation of a regular icosahedron.

Are the two real segments equal in the real model? NO

If they are not equal, which segment is longer? Why?

US is longer, it goes all the way across the 3D figure and RT goes by the edge of the figure.

Figure 9. Mary's answer sheet in the GSP version of the test.

representation provided allowed her to realize the congruence of segments US and RT. This time, she was able to visualize segments US and RT as diagonals of two pentagonal cross sections of the solid. Even though she did not mention this explicitly in her explanation, she did indicate the new visualization by shading these two pentagonal cross sections in the figure (Figure 9). Her idea was clearly that the two pentagons were congruent, and hence the two corresponding diagonals were congruent. This is an indicator that she used logic properties to explain her new finding and achieved conceptual understanding of the relevant spatial relationships.

**The goal of enhancing the subjects' geometric thought by at least one van Hiele level was basically achieved.**

Through the teaching experiments of the research, all subjects made significant progress. We used modified versions of the van Hiele level test developed by Mayberry (1983) to measure the subjects' levels of geometric thought at the beginning of the studies and at the end of each phase. Of these tests, the questions on two-dimensional shapes were from Mayberry's instrument, while those on three-dimensional objects and the criteria for scoring were created by us following the structure of her instrument. By the end of Phase 2, all subjects' geometric thought was found to be

improved with the increase of at least one van Hiele level. By the end of the research, all four subjects who participated in the teaching interviews in Phase 3 and Phase 4 improved their geometric thought by at least two van Hiele levels. Two of them (Manuel and Pedro) were able to do logical reasoning for the three-dimensional tasks, reaching the Deduction level (van Hiele level 4). For example, Manuel showed what we consider van Hiele level 4 thought in a variety of tasks. In the task shown in Figure 10, the front of an Archimedean solid was provided on paper. This solid is characterized as being composed of a pair of squares and a pair of equilateral triangles at each vertex. Manuel was asked to draw (on paper) a new solid from which this solid could be sliced. This task was quite challenging because it required considerable knowledge of Platonic and Archimedean solids, as well as strong three-dimensional visualization. Manuel easily completed the diagram (of the Archimedean solid) by drawing the hidden parts of the solid. He was then able to complete drawings of both a cube from which this solid could be sliced and an octahedron from which it could be sliced.

*Figure 10.* A sketch of an Archimedean solid characterized by the completion of the backside outlines.

*Figure 11.* The sketch of one of two Platonic solids from which the Archimedean solid is "sliced."

Figure 11 shows the octahedron that he drew. This indicates that Manuel was easily able to use the two-dimensional representations of the octahedron and the cube to produce the Archimedean solid. This task represents an example of complex problems that require mental processing equivalent in thought to that of a geometric proof. Sufficient GSP experience effectively helped him develop solid conceptual understanding so that he was able to solve challenging problems with or without referring to GSP representations. We believe that with consistent performance on such tasks, the subject was performing at level 4 in van Hiele's scheme.

Another example is the following task assigned to Pedro: Construct an Archimedean solid that is defined by the characteristic of having three squares and one equilateral triangle at each vertex. Pedro responded to this challenge by first drawing what he conjectured the solid would look like (see Figure 12). He then proceeded to create

*Figure 12.* A drawing of the Archimedean solid that has three squares and an equilateral triangle at each vertex.

*Figure 13.* A dynamic GSP version of the Archimedean solid.

a dynamic GSP version of the solid shown in Figure 13. The complexity of the task was substantial. Pedro started with a “local definition” of the solid and proceeded to a paper and pencil drawing. The drawing carried with it analysis and detail so that Pedro was able to discern the structure of the solid. He was then able to construct a dynamic GSP sketch with capabilities of rotation and creation of cross sections. This seems to be indicative of the nature of deductive reasoning, and leads us to believe that this student was functioning at level 4.

Dixon (1997) found in her study that GSP instructional environment was not more effective than the traditional environment at improving students’ three-dimensional visualization. However she suggested that the (test) result might have been different if the three-dimensional visualization had been measured using manipulation of blocks or the simulation of three-dimensional behavior using the computer. The results of these studies supported her conjecture.

### Conclusion

Three-dimensional visualization is a complicated cognitive procedure in which the subjects need to process the information perceived from external representation and the information retrieved from internal representation in an interwoven, integrative, and dynamic manner. During the studies reported by this article, the subjects actively participated in the explorations of three-dimensional visualization in the GSP dynamic instructional environment. Through interacting with the dynamic environment the subjects had many opportunities to construct their understandings of spatial structures and spatial relationships of three-dimensional objects. The way that the GSP environment differs from the traditional environment is that the GSP environment can provide students with dynamic two-dimensional representations of three-dimensional objects, powerful transformation tools, and some other useful features such as animation and the use of buttons. Specifically, the GSP environment helps students concen-

trate on the logical rather than visual properties of the three-dimensional objects. The immediate feedback provided by the dynamic environment allows students to verify or change their conjectures. At the end of the studies, the subjects had progressed significantly in terms of their van Hiele levels of geometric thought. In summary, GSP and the associated activities had a distinct positive affect on the subjects when they were developing three-dimensional visualization and pursuing conceptual understanding of geometry content.

### Acknowledgements

Preparation of this article was supported in part by a grant from the National Aeronautics and Space Administration.

Phase 1 of the studies had a basis in Jim Rodgers' master thesis. Phase 2 of the studies had a basis in Jinbing Zhang's master thesis.

## COGNITIVE ELEMENTS OF STUDENTS' USE OF METAPHORS IN A COLLEGE GEOMETRY CLASS

Norma Presmeg

npresmeg@ilstu.edu

Jennifer Bergner  
Salisbury University  
jabush@ilstu.edu

The aim of the research, of which this paper reports a part, was to obtain a deeper understanding of factors that enhance or inhibit the learning of mathematics in a university-level geometry course. In particular, the study investigated what metaphors and other forms of analogy were constructed by students in the course. These analogies provided a window into the developing geometrical conceptions of the students. In order to attain these goals, this research implemented a qualitative case study methodology using action research. This paper reports on a preliminary analysis of the metaphorical ideas of point, line, and plane of 16 students, with an in-depth analysis of the responses of two of these students.

### Theoretical Framework

In the mathematics education community there has been a recent interest in the metaphorical basis for mathematical thinking and reasoning, not only as an aid to learning, but as the very substance of mathematical thought itself (Lakoff & Núñez, 2000; Núñez, 2000). Theoretical formulations have argued persuasively that metaphor and other forms of analogy are important components of mathematical cognition, and thus should be taken into account in its teaching and learning (Sfard, 1997). However, there are very few empirical studies that have investigated the role of metaphors in high school mathematics education (e.g., Presmeg, 1992, 1997), and even fewer at the collegiate level (e.g., Sfard, 1994). Thus we aim to fill a lacuna in the literature on metaphor use in mathematics education by investigating how students in a university course, College Geometry, use metaphor and other forms of analogy to make sense of geometrical concepts. Our theoretical framework, grounded in the literature cited in the foregoing, includes the linking of target and source domains through metaphors in which the source consists of familiar elements of everyday life (for example, containers) and the target domain is a mathematical construct (for example, sets, as used in set theory). In addition to the basic grounding and linking metaphors described by Lakoff and Núñez (2000), we acknowledge that there are idiosyncratic metaphors designated by these authors as "extraneous", which may nevertheless play a vital role in the learning of mathematics by individual students (Presmeg, 1992). Thus our framework is wide enough to encompass all of the spontaneous links between source and target domains constructed by the students in the study during their learning in the geometry course. Because of the exploratory nature of the study, we did not make a fine distinction between use of simile and use of the corresponding metaphor (e.g., "a point is like a period on the end of a sentence", vs. "a point is a period...").

In the broad study, because we are interested in the personal constructions of individual students and how these might be reflexively implicated in and influenced by social interactions during the geometry course, our theoretical framework resonates with the emergent perspective of Cobb & Yackel (1995), in which social and psychological lenses are used to interpret the varied phenomena of learning, in this case in one university geometry class. In the present research we focused on the psychological dimensions as a starting point. There is one further strand in the theoretical formulation of the research issues that we wanted to be sensitive to, although it was not a focus in this study. Some metaphors constructed by individual students may be highly personal, charged with affective meaning. Thus it would be valuable to take into account both cognitive and affective elements of the use of metaphor in geometry, for instance, using Goldin's (2000) model of affective pathways, which involve "not global attitudes or traits, but local changing states of feeling that the solver experiences and can utilize during problem solving" (p. 209). There were hints of the emotionally charged nature of some uses of metaphor in the research reported here.

### **Methods of Inquiry**

Because this research involved one university class during one semester (spring, 2002), it may be conceptualized as a bounded study. A qualitative case study (Merriam, 1998) is appropriate to the objectives. Thus the methodology is qualitative and interpretive, and the methods of inquiry include surveys (initial and at the end of the course), clinical interviews with selected students, and observations during whole class and small group sessions throughout the semester, as well as collection of students' work. Both researchers were present at most of the class sessions, one as observer, and the other as teacher of the course – thus introducing elements of action research into the methodology (Kelly & Lesh, 2000). Quality of the research will be monitored through triangulation of data sources, through respondent validation, and through coordination of the interpretations of the two researchers and the students involved.

All of the 17 students in the course gave their consent to use of the survey results in this research. We have complete journal entries from 16 of the students. Thirteen students agreed to participate actively through interviews and detailed classroom observations. Six students (three women and three men to balance the genders) were selected from the thirteen students for clinical interviews. Selection was based on the initial visualization survey results to include visualizers and nonvisualizers (see next section), because previous research findings had suggested that preference for visual imagery might be a factor in the students' construction of metaphor (Presmeg, 1992). In the following section, the data sources are described.

### **Data Sources**

An attitude survey was administered to all students during the second week of the course. In addition to initial questions relating to their previous experiences of

geometry, students responded on a five-point scale to 38 questions that addressed their conceptions of the nature of geometry and how it should be taught, followed by a free-response section entailing related questions (e.g., question 1, "Please describe how your previous teachers presented and explained geometric concepts. How did this make you feel about geometry?" 5, "What do you consider geometry to be?") A modified form of the same survey was administered again at the end. The purpose of the survey was to provide baseline data and to monitor changes through the course in a global fashion. More detailed information was provided from other data sources.

A "preference for visualization" instrument was administered on the first day of the course (Presmeg, 1985). Students completed 12 everyday problems using whatever method was comfortable for them (all problems could be solved using either visual or nonvisual means). Then they completed a questionnaire that asked them to identify the methods of solution they had used. Visual solutions (written or imagined) yielded a score of two points, nonvisual solutions zero, giving a possible total of 24 points on a "mathematical visuality" scale. The purpose of this instrument was to identify the "visualizers" in the class, that is, those students who prefer to use visual imagery or diagrams in solving problems that may be solved with or without these methods, in case preference for use of imagery was a salient factor in the representation they chose for geometric analogies.

Students submitted reflective email journal entries each week of the course. In the first journal entry, they were asked to expand on the two questions, "What is geometry to you?" and "How would you like to learn geometry?" In subsequent entries they reflected on experiences in the class, and on geometry learned that week and how they felt about it. The journals had the twofold purpose of establishing a line of ongoing communication, and of providing data relating to cognitive and affective aspects of students' learning. Students were also asked in specific journal entries to address their notions of proof, and their metaphors for point, line, and plane.

The six students who were selected from the 13 who agreed to full participation discussed cognitive and affective aspects of their mathematical concepts during the interviews. These interviews were video- and audio-recorded because body-language might have been important (not addressed in this paper).

### **Preliminary Results**

The survey results are in the process of being analyzed. The "preference for visuality" instrument yielded scores ranging from 2 (nonvisual) to 22 (highly visual) out of a possible 24, with a class median of 12. Students with extreme scores were included amongst those interviewed. The scores of the six students chosen for interviews ranged from 6 (nonvisual) to 22 (highly visual). It was mainly in the interviews that metaphors were investigated in depth, but students' journal entries and classroom observations also yielded metaphors. Metaphors and analogical reasoning abounded while class participants were talking about solids, non-Euclidian geometry, tessellations, and defining concepts such as point, line, and plane. No use of analogies was

explicit throughout the middle of the course while students were tackling the Hilbertian style of proof and working through proofs involving standard geometric theorems.

Some of the richness of the spontaneous idiosyncratic metaphors generated by various students can be gleaned from the following list:

- a truncated pyramid is a sliced chunk of cheese;
- the x-axis on a coordinate plane is water level;
- an icosahedron is the interlocking jaws of a monster;
- a slide (translation) is a raindrop going down a window;
- the discovery of “tessellations” is like the discovery of America: they didn’t really invent it but they named it “America”.

These analogies arose in the interviews, or were generated in class discussion. Some of these were explored in greater depth with the students but these are not a focus in this paper. In the next section, after an in-depth description of two students’ use of analogies for point, line, and plane, we provide a general overview of 16 students’ metaphors for these concepts.

### **Conceptions of the Concepts of Point, Line, and Plane**

The constructs of point, line, and plane are usually taken as undefined terms in the axiomatic system of incidence geometry (Rainich & Dowdy, 1968). They can be viewed as building blocks upon which the edifice of a geometry course can be laid. The text used in their class, *College Geometry* (Kay, 2001), adopted the formal system found in Moise’s *Elementary Geometry from an Advanced Standpoint*, an adaptation of Hilbert’s original axiomatic development of elementary geometry. Point, line, plane, and space were taken as undefined terms. However, in class, the instructor stressed that the visual representations of points, lines, and planes were not the theoretical constructs themselves. We now take a closer look at the development and maturation of these ideas in the eyes of two college geometry students to whom we have given the pseudonyms Jane and Mary.

#### **“A point is that which has no part” – Euclid**

Initially, both conceived that a point was tiny. Mary believed that any dot on a piece of paper was a point and expressed amazement that until this course, she did not realize that a point was actually just represented by that dot. She implied during the second interview that she was shocked a point was not a dot because her high school teachers had always told her it was. She added, “Those who are going to major in math can think about this so that when they get to college they are not so shocked when someone says that to them.” Even though she felt it was important for her and other mathematically inclined students to understand the theoretical conception of a point, she made sure to state, “It’s not that our high school teachers were lying to us, they just did not think we needed to know that.” Jane appeared to struggle less with

reconciling the current definition of point with her previous notions, stating, "I think of the points you are looking at when you look at a piece of paper...I have a theoretical image of a point: that it's as small as you can possibly get. There is nothing actually there, but there is." Jane appeared to be realizing that there were two ontological entities involved, namely, the representation of a point and the point itself.

Mathematically, a point is dimensionless. It has no size, even though our bodily experience suggests to us that if a point is a fundamental component of lines, planes, and solids, then it must have size, else how else could it exist? The students struggled with this idea of a nothing that is, just as Euclid and his contemporaries did. This is best seen by considering that Aristotle adopted the definition given by the Pythagoreans: "that which is indivisible in every way in respect of magnitude and without magnitude but has position" is a point. Plato apparently objected to this definition because it implied that points were a "geometrical fiction". Euclid, himself a Platonist, omits that a point must have position (Heath, 1956). Trying to reconcile a something that has no dimension was implicated in Mary's statement, "It's there, it exists but you can't see it. It's hard for me to understand but I guess a point is there but you don't actually see and it's like microscopic- it's not there- it's teeny, teeny, tiny," and Jane's statement "There is nothing actually there, but there is. I think of it in terms of an atom. I can't really look at an atom in a microscope or anything like that but I know what it is." Interestingly, the concept of a point being an indicator of position did not explicitly appear in any discussion with or journal entries of Jane and Mary, although it might have been implicit in Mary's journal-entry metaphor, "a point is a star in the sky".

As indicated by the journal entries detailing students' personal metaphors for point, submitted in the last weeks of the course, Jane and Mary decided that a point was smaller than they could conceive. As another student (who has not been interviewed at this time) pointed out, a point is a grain of salt in a beaker of water just before it dissolves. In these journal entries they appeared to be reconciling this notion of no size versus existence by providing metaphors for point that likened a point to something that was really small compared to its surroundings. Comparably to Mary's macroscopic metaphor, "A point is a star in the sky," Jane likened a point microscopically to "an atom in one of the paper fiber molecules used to make a thin piece of paper."

During the final interview, the students were asked once again to discuss point, line, and plane. They also were presented with a table that had point, line, and plane paired with the descriptions their classmates had provided in their last journal entries. The students were asked which pairs seemed alike or not alike and to explain their reasoning. Jane and Mary still focused on the size. In discussing their choices they both emphasized the importance of choosing objects that were small compared to their surroundings. Jane claimed to have used her chemistry background to adjust her final journal entry metaphor to become a point "is a fraction of a proton." Mary's initial conception that any dot was a point (which she always drew as a small circle) seemed to manifest itself in her justifications for her metaphor selections. Her favorite, a point is a pinprick, was selected because a pinprick is "precise and is circular".

This leads to the question of whether Mary's use of metaphor to describe point is actually restricting her to a concrete understanding of the notion of point. Or is it the nature of undefined concepts to be difficult? Historically, there has been much discussion on how to describe a point. In modern times, geometers have tried to circumvent the problem by actually using objects from the material world as illustrations from which the concept is abstracted (Heath, 1956).

### **"A line is breadthless width" – Euclid**

Both Jane and Mary, when initially asked to define line, immediately defined straight line. By the end of the course Jane seemed to become aware that the word line triggered the concept of straightness for her, but it was unclear whether Mary had this self-knowledge. Mary initially defined line as a "sequence of points that are connected" and "it's just a group of points lined up — together, one on top of the other all touching." This original definition manifested itself at the end of the course in her personal metaphor "a line is a string of beads", which was chosen because "the beads are all strung up like the points are on a line."

The attribute of straightness was important to her throughout the course. When asked how she would describe a line to a child she initially sketched a line and then remarked that it was not straight enough and proceeded to fold a corner of the paper and point to the crease as a good example of a straight line. This also seemed to indicate that the attribute of infinite length was not as important to her. In the final interview, some of her preferred metaphors, a line is "a dividing line on a road because it is thin", or a line is "a straight edge of a ruler" indicate that she still focused on the straightness of a line and also on her perceived thinness of a line. It appears she saw a line as having some kind of thickness if we take these together with her comment that length and distance are not good metaphors for line because "they cannot be seen and a line can be seen." None of the discussion in the third interview indicated a need for a line to have infinite length. A slight indication that Mary saw a distinction between line and the concept of straightness appeared when she explained why a piece of rope was a good metaphor: "this one is good because you can bend a rope around into different shapes like a line." However in the same interview, when asked what she thought when she heard the word line in geometry class, she stated, "Shapes, what shapes are made of — you *bend* a line into the different shapes."

Jane appears to have an early conception that a sketch of a line is a representation and that a line must have infinite length: "the line would be something that has a distance but you can't ever tell how thick it is and because in order for you to draw it you would have to give it thickness you can't ever really draw a line." During the last interview, Jane acknowledged that when asked about a line she immediately thought "straight, in the Euclidean sense", until their exposure to taxicab geometry. In her early descriptions she also used the Archimedean property of a straight line, "the short-

est distance between two points and the fastest way to get between those two points in space.” By the last interview, Jane stated that any representation of a line should involve an infinite set of points, have no start or end, and was straight in the “Euclidean sense”. When discussing which metaphors she preferred, she primarily focused on the last two properties. The metaphor, “a line is an arrow with no surrounding forces (like gravity) acting on it”, was rejected because it had a visible starting point. Another rejected metaphor, a line is a road, did not work because “I have seen too many curved roads.”

In these metaphors, the issues that arose were straightness as an attribute of a line, and dimensional attributes of length and width in the representations. The metaphors appeared to bring these issues to the fore. The discussion in the interviews facilitated reflecting by the students, without pre-empting by the interviewer. This was also the case in the discussion of metaphors for a plane.

**“A plane surface is a surface which lies evenly with the straight lines on itself”  
– Euclid**

Both described a plane as a flat surface that contained points and lines throughout the course. Jane stated that she still thought of a plane as it was initially described to her: “a sheet of paper that keeps on going forever but its so thin that you can’t even see it because its only the thickness of a point.” She also included the condition that you can’t curve the paper because a plane must be flat.

Mary also claimed that a sheet of paper would be a plane and justified this by saying a plane is “just where you could draw points and lines.” She also stated that a plane could have any size, paper was just a plane in “minimized area” and that “you could extend it as far as you wanted to. Mary implied that her notion of the size of a plane had changed by stating that the faces of a tetrahedron would be “parts of planes” and that a circle is a “cut-out” of a plane. In the last interview, both Jane and Mary found the metaphor “a plane is a chalkboard” the best because it was a flat surface that would contain lines and points. Jane also mentioned that this was a good metaphor for a classroom because it was convenient.

Jane was very careful to always include a disclaimer of infinite size in all of her descriptions of plane. With the chalkboard she stated, “it goes on thru earth and its sides extend forever”, and she liked the metaphor “plane is a wall” because she stated that with a wall you could think “longer than the great wall of China and however tall.” Her choice of metaphors for plane also seemed to indicate that the concept of zero thickness was important to her. She rejected a pane of glass because she imagined seeing it from the side and substituted a plane is “a sheet of infinitely long saran wrap.” When reminded that a chalkboard also has thickness she remarked that you do not look at it from the side.

In these metaphors, Jane and Mary both seemed to realize that the plane extends infinitely, even if the piece of paper or the chalkboard do not. This is a dimensional

issue. The other dimensional issue of thickness was addressed by Jane very explicitly (“paper one atom thick”), but not by Mary, who predominantly focused on the flatness attribute of a plane.

### **General Overview**

From the final interview discussions with Jane and Mary, the text’s discussion, Heath’s translation and commentary of Euclid’s Elements, and the researchers’ understandings of the concepts of point, line, and plane, the two categories, dimension and structure, for the attributes of the three concepts emerged. Dimension contained the attributes of size (length, width, height) and structure included attributes of the nature of the object such as its position, shape, or relationship to other objects. In the following we discuss the metaphors that 16 students (including Jane and Mary) provided for point, line, and plane in their metaphor journal entries according to these two categories.

As discussed earlier, a point is dimensionless. Although asked to create a metaphor for a point, one student chose to provide defining attributes of the point such as “a point on a plane has no space but has a definite position.” One student provided a simile “a point is like the period on the end of the sentence,” and the remaining 14 provided 21 metaphors for point. Most of the metaphors (16 of 21) likened the point to an object that was small: “a point is a microchip” or to an object that was small compared to its surroundings: “a point is a baseball stopped in space.” Three of the 21 analogies for point had no size and were also the only metaphors that referred to the position aspect of point, a point is “an imaginary number”, “a place but not a spot”, “a designation.” Four of the students did use the metaphor a point is dot; one called it invisible, another mentioned it was a dot with no length or width, and two put no qualifications on the point. It is not known if the last two realized that a dot is the physical representation of a point or if like Mary they thought that a point was the dot. Some of the 23 responses are shown in table 1.

A line is infinite in length but with no thickness. Of the 22 responses provided by 16 students, 19 were metaphors, three were similes. 13 of the responses provided for the attribute of infinite length including such adjectives as never ending, infinite, forever. Four of the responses explicitly addressed the fact that a line should have no breadth or width. Six of the responses appeared to address the breadth issue, “a line is a never-ending straight path to any destination you wish...” The other responses included such items as a line is “a never ending string”, “the horizon” and could be interpreted as referring to the width issue. Some of the 22 responses are shown in table 2.

Overwhelmingly, the 15 students likened a plane to a flat surface such a chalkboard, sheet of paper, wall, or pane of glass. Two students provided mathematical descriptions for a plane such as “a two dimensional region of space.” Of the 26 responses, seven addressed the infinite size attribute explicitly by using such words

**Table 1.** A Selection of Students' Metaphors for a Point

| A point is ...   | Dimension                      | Structure |
|--|--------------------------------|-----------|
| a dot (two students)   | small                          | circular  |
| the size of a pea in space, only infinitely smaller                  | small compared to surroundings |           |
| a star in the sky  | small compared to surroundings |           |
| a period at the end of a sentence                                    | small compared to surroundings | circular  |
| atom   | small                          | component |
| grain of salt dropped in a beaker of water right before it dissolves | small                          | position? |
| a spot within an area  | small                          | position  |
| a space, but not a spot  | no size                        |           |
| an atom of one of the fiber molecules used to make thin paper.       | small compared to surroundings | component |
| microchip  | small                          |           |
| imaginary number   | no size                        |           |

as never ending or infinite. Two of the metaphorical responses commented on a plane having the mere thickness of a point and only extending in two dimensions. Some of the 26 responses are shown in table 3.

This paper could address only a small part of the study, and the analysis is ongoing. The categories of dimension and structure were grounded in the metaphors generated by the students. The eliciting and discussion of the students' metaphors turned out to be a powerful research tool that allowed for deeper probing of their understandings of point, line and plane. Because many of the students' metaphors were new to the researchers (although they were very familiar with concepts of point, line, and plane), these novel ways of thinking enabled the researchers to search more deeply for what the students meant, and to probe further by questioning. Instead of using a geometrical task or problem in the interviews, the discussion of the metaphors generated by these

**Table 2.** A Selection of Students' Metaphors for a Line

| A line is ...  | Dimension       | Structure         |
|--|-----------------|-------------------|
| a ray of light   | infinite length | straight and thin |
| a straight road  |                 | straight          |
| a stretched piece of rope  |                 | thin              |
| a piece of straw   | finite length   | straight          |
| an infinitely long marker that separates two lanes of traffic on an infinitely flat road | infinite length | thin              |
| a never-ending string  | infinite length | thin              |
| the horizon  | infinite length | straight boundary |
| an arrow with no surrounding forces (like gravity) acting on it                          | infinite length | straight and thin |
| a string   |                 | thin              |
| a never-ending telephone wire  | infinite length | thin              |
| a path that never ends   | infinite length |                   |
| a hockey puck path (with no friction to stop it) in an arena with no walls               | infinite length | straight and thin |

students and others provided a window for starting to understand their notions of the nature of point, line, and plane, and the connections between these concepts and their physical representations.

## WRITING CONJECTURES IN GEOMETRICAL ACTIVITIES WITH CABRI-GÉOMÈTRE

mercado@mail.cinvestav.mx

We present here some advances concerning a project whose aim is to explore the relationships existing between the geometrical activities resulting from some students' activities in an environment of dynamic geometry (using Cabri-Géomètre software, in this case) and the production of written formulation of conjectures and proofs. The study was carried out with eight senior high school volunteer students, 16-17 year-olds, who had previously attended a Euclidean Geometry course of one semester in a public school.

The Cabri-Géomètre scenarios help the student to accede to the knowledge of geometrical facts. The validation of these facts is based on the "dragging" technique. This is an exploration tool that helps the student to discover the invariant relationships that are present in the geometrical constructs (Hölzl, 1996).

In the production of this knowledge some input texts (instructions), the student's interaction with software, and the geometrical representations produced and perceived on the screen are all involved. However, according to standard mathematical criteria, the scientific consolidation of these geometrical facts demands that they be constituted in a system of results that needs to be expressed in written argumentation and in a language adapted to the demands of deductive proofs. Hence, the importance arises that conjectures and propositions are formulated in writing.

Furthermore, writing, usually, and also oral language, gives shape and precise meaning to thoughts or ideas, which previously lacked exact contours. When this happens, not only the existing thought is transferred into a written, or oral formulation, but also, in doing so, it is modified and it is given a precision of which it lacked, making it remarkably clearer.

In the case of students' geometrical ideas, their activity with dynamic geometry allows them, even before the writing phase, to have a representation which is free of ambiguity and imprecision, and also gives them a conviction of the validity of such ideas; and this representation should help them to make a written formulation, since their linguistic competence is now acting on a less unshaped material. A question, however, arises. How does the representation of data processing of geometrical facts help the students to accede to the possibility of writing the representation of such geometrical ideas?

### Background

Some researchers have recognized the importance of the role played by oral and written language in understanding mathematics (Duval, 1995; Laborde, 1990, 1992; Pimm, 1987); and including *communication* (oral and written) as a standard process in

NCTM (NCTM, 2000) is a demonstration of that assertion. On the other hand, studies about mathematical proof have highlighted features that are making clear the complex field of mathematical proof: the role played by empirical evidence in contrast with deductive arguments (Chazan, 1993; Martin & Harel, 1989); the difference between argumentative reasoning and deductive reasoning (Duval, 1991); and the students' proof schemata (Harel, 1996). Particularly, with the arrival of computers, the problem of the influence of activities with dynamic geometry on learning mathematical proof has been posed (Hoyles & Jones, 1998; de Villiers, 1998). Balacheff (1987) emphasizes the role of language in the passage from pragmatic proofs to intellectual proofs. In spite of his remarks about the importance of formulating situations, the results about conjecture processes (Kakihana, Shimizu, & Nohda, 1996; Boero, Garuti & Mariotti, 1996) do not consider the difficulties imposed by language, which enrichment and broader usage could open an access to proof. In our study, we consider that possibilities provided by dynamic geometries could allow us to reconsider the relationships between the language and mathematical proof since the very moment of discovery and formulation of conjectures.

### Experience Design

In the summer of 1999 we organized a geometry workshop with eight senior high school students (16–17 years old) who were volunteers from a public school (IPN) in Mexico City. They had attended a geometry course. In eight four-hour sessions, distributed along two weeks, they were taught to use the software (Cabri-Géomètre). Then, they were asked to do some activities in order to remember basic facts of geometry and other activities so that they could discover relationships between the medians and the areas of a triangle. The activities were taken from a document from the teamwork of Cabri (Équipe EIAH, 1996).

Each student worked individually. We counted on the support of four observers and each one of them was assigned to two students. The observers had the permission to intervene in order to help students only with the related difficulties of software use, without giving their opinions about questions of mathematical content. Moreover, each instructor wrote down the most relevant facts observed from the students' activities. We have considered in this report only the instructors' remarks that plainly show whether each student arrived to the correct conclusions of each activity.

In order to analyze the written productions, we considered the correct syntax of the statements (i. e., we observed whether the sentences obeyed elemental grammatical rules of language (Spanish) and whether the expressions in natural language were coordinated adequately with the geometric symbols and with the figure).

Another criterion more specific consisted in the comparison of the statements with the conditional structure ( $P \Rightarrow Q$ ) of the corresponding proposition. In particular, we observed whether the statements each student wrote had a complete description of the antecedent. This feature would tell us if a conjecture was conceived as a complete proposition, in which the formulation of the antecedent is fundamental.

We observed in a punctual way whether a student formulated the propositions without making reference to the figure or if he/she used it to facilitate its expression. The use of symbolic notation tied to the figure mitigated considerably the difficulty in expressing the geometric ideas.

Summing up, the following three aspects help us to get closer to the texts produced by students: A) Correct syntax; B) Complete description of the antecedent; C) The support of the text on the figure and the use of symbols.

### The Conjectures

The propositions to which the activities we posed to the students could lead, constitute a system in the sense that a proposition can be deduced from other (or others) previous proposition(s). The propositions related medians to areas of triangles. We set them forth as they are below in a conditional form.

*Theorem 1:* If in the triangle  $\triangle ABC$ ,  $AM$  is a median, where  $M$  is the midpoint of  $BC$ , then  $\text{Area}(\triangle AMB) = \text{Area}(\triangle ACM)$

*Theorem 2:* Consider a triangle  $\triangle ABC$  and a median  $AM$ , where  $M$  is midpoint of  $BC$ . The height of triangle  $\triangle ABM$  that departs from the vertex  $B$  is congruent with the height of triangle  $\triangle AMC$  that departs from the vertex  $C$ .

*Theorem 3:* If in the triangle  $\triangle ABC$ ,  $M$  is an inner point so that  $\text{Area}(\triangle AMB) = \text{Area}(\triangle ACM)$ , then  $M$  is upon the median  $AX$ , where  $X$  is the midpoint of  $BC$ .

*Theorem 4:* Let  $\square ABCD$  be a trapezoid, with  $AB \parallel DC$ . Let  $S$  be the point of intersection of the extension of the sides that aren't parallel (i.e.,  $S = AD \cap BC$ ) and let  $I$  be the midpoint of  $AB$ . Then, segment  $SI$  is a median of  $\triangle ABS$ . Let  $X$  be the point of intersection of the beam  $SI$  with segment  $DC$ . Then segment  $SX$  is a median of  $\triangle DSC$ .

*Theorem 5:* Consider a triangle  $\triangle ABC$  and let  $A'$  be the symmetrical of  $A$  with regard to  $C$ ;  $B'$  the symmetrical of  $B$  with regard to  $A$  and  $C'$  the symmetrical of  $C$  with regard to  $B$ ; then  $\text{Area}(\triangle A'B'C') = 7 \times \text{Area}(\triangle ABC)$ .

*Theorem 6:* The medians of a triangle divide it in six triangles with equal areas.

In the following, we present activities 1 and 3 that were posed to the students in the second phase of the workshop.

#### Activity 1

- Construct a triangle; label the vertexes with  $A$ ,  $B$ ,  $C$ .
- Mark the midpoint of segment  $BC$ , calling it  $I$ .
- Define triangles  $\triangle AIB$  and  $\triangle AIC$
- Obtain the areas of triangles  $\triangle AIB$  and  $\triangle AIC$ .

- Grab any vertex A, B, or C and drag it to a new position. Observe what occurs with the obtained areas.
- Write a conjecture about your observation and write the corresponding test.

### Activity 3

- Draw a triangle, label the vertexes with A, B, C and elect a point M in the interior of the triangle; create triangles  $\triangle ABM$  and  $\triangle ACM$  and include their areas; construct semi-straight line AM, name X the intersection AM with BC. Include the measurements of segments BX and XC.
- Move point M until you have achieved that the areas of triangles  $\triangle ABM$  and  $\triangle ACM$  are equal or almost equal. What can you now say about the position of X?
- Can other positions of M be found for which the areas are equal? What conjecture can you formulate for the position of X? Write it down.

Upon carrying out the previous activities, students would have formulated theorems 1 and 3 enunciated above.

### Observations and Analysis

In order to refer to the students we have numbered them from 1 to 8. According to the observers' reports, activity number 3 was one of the most problematic ones. Although all students made the construction they were asked and they related the pertinent aspects, that is, the equal areas with the inner point placed upon the median, they were not able to distinguish exactly what they were asked. They enunciated the inverse proposition. However, they were not aware of their confusion. Only the observer perceived they were confused.

In the rest of the activities, except for two other cases, all the students made the construction adequately and "saw" what the activity was about. Student number 4 could not organize the activity number 4 very well and student number 8 got confused with activity number 5. So, in general terms, we can affirm that the students noticed the reason why these activities were conducted.

On the other hand, their achievement on writing the corresponding propositions was very poor. If they were evaluated with certain rigor, almost all the statements had mistakes. In spite of them, the authors unified the criteria to decide which statements could be considered correct in the sense that they expressed the asked idea; in the following frame we indicate with the ones that were evaluated as correct and with number 0 the ones that were considered as incorrect (See Table 1).

Based on the pointed out categories, we would like to summarize the students' observations in the following chart 'Student by Activity' (See Table 2). In the columns with the heading "A", numbers are assigned in relation to the correct syntax of the

Table 1

| Student    | 1 | 2             | 3 | 4 | 5             | 6             | 7 | 8 |
|------------|---|---------------|---|---|---------------|---------------|---|---|
| Activity 1 |   |               |   |   | $\frac{1}{2}$ | $\frac{1}{2}$ | 0 |   |

|         | A | B | C | A | B             | C             | A             | B             | C | A             | B | C | A             | B             | C             | A             | B             | C | A | B | C | A             | B             | C |
| 1       | 1 | 1 | 0 | 1 | 1             | 0             | 1             | 1             | 0 | 1             | 1 | 0 | $\frac{1}{2}$ | $\frac{1}{2}$ | 0             | $\frac{1}{2}$ | 1             | 0 | 0 | 0 | 0 | 1             | 1             | 0 |
| 2       | 0 | 1 | 0 | 1 | 1             | $\frac{1}{2}$ | $\frac{1}{2}$ | 1             | 1 | 0             | 0 | 1 | 0             | 1             | 1             | $\frac{1}{2}$ | 1             | 0 | 0 | 0 | 0 | 0             | 1             | 0 |
| 3       | 0 | 0 | 1 | 0 | 0             | 1             | $\frac{1}{2}$ | 1             | 0 | 1             | 0 | 0 | 0             | 0             | 1             | 0             | 0             | 0 | 0 | 0 | 1 | $\frac{1}{2}$ | 0             | 1 |
| 4       | 0 | 1 | 0 | 0 | 0             | 1             | 0             | 0             | 1 | $\frac{1}{2}$ | 0 | 0 | $\frac{1}{2}$ | 0             | 0             | 1             | 0             | 0 | 0 | 0 | 1 | 0             | $\frac{1}{2}$ | 1 |
| 5       | 1 | 0 | 0 | 1 | $\frac{1}{2}$ | 0             | 1             | $\frac{1}{2}$ | 0 | $\frac{1}{2}$ | 0 | 1 | $\frac{1}{2}$ | 0             | 0             | 1             | 0             | 1 | 1 | 0 | 1 | 0             | $\frac{1}{2}$ | 0 |
| 6       | 1 | - | 1 | 0 | -             | 0             | $\frac{1}{2}$ | -             | 1 | 1             | - | 0 | 0             | -             | $\frac{1}{2}$ | $\frac{1}{2}$ | $\frac{1}{2}$ | 0 | 0 | - | 0 | $\frac{1}{2}$ | -             | 0 |

written propositions from the corresponding student. Number 0 has been assigned to the enunciations that violate several syntactical rules in a way that makes the enunciation very confusing. We assigned the fraction  $\frac{1}{2}$  to the statements that, although they are defective, they were able to transmit the meaning of the proposition. Number 1 was assigned to the statements that were judged to be totally correct. Naturally, the beforehand statements and the following ones reflect the point of view of the researcher and his collaborators; so, the assignments are somewhat subjective.

In the columns marked "B", we grade the complete description of the antecedent with 1 if the enunciation is present and with 0 when it is absent; we have placed  $\frac{1}{2}$  when it is difficult to decide between both extremes. Finally, with the category "support of the figure" the columns with the heading "C", we assign 0 if the enunciation is not supported by the figures nor utilizes symbolic notation, with 1 when elements of the figures are expressed through symbols such as P, PQ, AB, etc.

In the first two activities almost all students described the antecedent in their statements, but in the activities 3, 4, and 5 only in three occasions there was a complete description of the antecedent (in activity 6 it was not required to formulate the conjecture).

In several occasions inadequate words were used to refer to objects that students had already understood in the screen. For example, one of them uses *perpendicular*

*bisector* instead of *median* (in Spanish: *mediatriz* and *mediana*, respectively), another one uses *vector* trying to say *vertex*, another one writes *heights* of the triangle to designate the *sides* of the triangle others than the base.

We observed that the corresponding statements to activities 2, 3 and 4 display a bigger difficulty in the syntax. This could be happening because the complexity of the statements is greater and they demand specialized phrases that become complicated if the figure and the symbolic notation are not used, for example: “the perpendicular to the straight line... that crosses the point...”, “the areas of the triangle formed by the interior point to the triangle, the superior vertex and every vertex of the base segment are equal...”, “the triangle formed by prolonging the non-parallel sides of the trapeze...”.

The lack of vocabulary and of control in the formulation of appropriated phrases to describe the geometric objects, and the reluctance of the students to use symbols, make it harder for them to do the task. In effect, only in few occasions they utilize graphics and symbols. We had to consider that in some cases they needed to use symbolic notation.

We now present some observations regarding the students’ productions as answers to *Activity 1*. We noticed that there were two ways in which the question was understood. Four students properly understood that they were being asked to write the statement of the proposition on the areas of the triangles that are formed by means of the median. The other four gave more ample answers while trying to produce a proof. Only two students of the first group produced statements that, although not quite precise, they were syntactically and mathematically correct:

Student 2: The triangles formed when drawing the median of a triangle have equal areas.

Student 3: When dividing a side in half and then joining this point with the opposite vertex, the area(s) of the two triangles thus formed are always equal.

The other two students established syntactically incorrect statements, although we were able to ascertain that they were thinking in terms of the correct idea:

Student 5: The area of two triangles that are inside another one, whose side is the perpendicular bisector of one side of the first triangle, is equal for both.

Student 6: If in any triangle the middle point of a segment is obtained and when joining it with the opposite vertex, the area of such triangles thus formed are equal. If you obtain the midpoint of the base segment and this, when joined with the third vertex, the areas of the two triangles are equal.

Of those offering an argument, only one achieved an acceptable formulation, and another one almost succeeded:

Student 1: When drawing the midpoint in any side of any triangle, and when joining it with the vertex opposite to that side, the two triangles thus formed will always have the same area because the height is the same for both. And they will be compensated with each other.

Student 4: A median divides the area of the triangle into two equal areas. For, since they have the same common base, with the same dimension, in these two triangles their height will be the same.

The other two students formulated only redundant statements, without succeeding in arriving to an argument:

Student 7: They have the same area because when obtaining the midpoint, that is the median; and therefore, they have the same area.

Student 8: When in a triangle one of its sides is divided with a median, two triangles with the same area are formed, because such a median divides them in two exactly.

We can observe that, in spite of the fact that the students can show that they know the result, and that it furthermore convinces them, they find great difficulties when trying to formulate it correctly.

### Conclusions

Balacheff suggests that in order to accede to what is called mathematical proof, it is necessary that the student accede to a functional language that would not be only a way of describing the actions. Such language is characterized by the introduction of certain quantity of symbolism (Balacheff, 1987, pp. 58-59). Our observations show students' difficulty to accede to that functional language. Furthermore, we can say that it is necessary for the students to learn how to use the symbols. It is also important for them to acquire and use the vocabulary of geometry and learn the syntax of phrases that describe geometric objects.

The frame that a student requires in order to organize information with the purpose of carrying out a deductive geometric demonstration is different from the frame, which is required in order to have a certain control of geometric objects on the screen and observe behavior. Nonetheless, in the written activity a complexity is revealed which the software yields and hides at the same time. But beyond all doubt, different from the past, the activities with dynamic geometry can permit the explorations of the properties of the objects. Otherwise, as a consequence of this study, we would advocate that parallel activities of writing in all levels of education not be abandoned.

# SHAPES, ACTIONS AND RELATIONSHIPS: A SEMIOTIC INVESTIGATION OF STUDENT DISCOURSE IN A DYNAMIC GEOMETRIC ENVIRONMENT

It has been argued that trying to describe ways in which students interact in dynamic computer environments may extend beyond Piagetian developmental levels and stage theories of learning (Connell, 2001; Doerfler, 1991). Therefore, the purpose of this study was to use a semiotic perspective to describe the discursive activity of students learning about quadrilaterals in a dynamic geometric environment. During a two-week lesson study, the onscreen work and dialogue of two students was captured on a video recorder. An analysis of the students' discourse gave evidence that students concurrently construct their understanding of properties and relationships between different quadrilaterals. Furthermore, the students seem to treat the on-screen-geometric representations as mathematical objects within themselves and not as geometric tools.

Within the last decade, rapid developments in computer technology and mathematical software have given students of mathematics new means by which mathematical objects and relationships can be visualized (Battista, 2001; Connell, 2001; Sfard, 2000). For example, dynamic geometric software allow students access to mathematical shapes that may be manipulated and morphed while preserving the defining properties that make up that shape. Due to this action on object capability that dynamic geometric software provide, it has been argued that the trying to describe ways in which students interact in these computer environment may extend beyond Piagetian developmental levels and stage theories of learning (Connell, 2001; Doerfler, 1991). In order to investigate this claim, this teaching experiment examined the nature and development of student discourse in a computer based dynamic geometric environment using a semiotic framework of inquiry. The emphasis of the study was to document and describe how fifth grade students visualize and conceptualize the dynamic on-screen representations of quadrilaterals in an interactive hypermediated environment. In particular, in what ways do the students' discursive activity about these on-screen representations differ from more traditional discourse about quadrilaterals.

## **Actual Reality, Virtual Reality, and Prototypes**

The initial context for this investigation lies in what Sfard (2000) calls actual reality (AR) discourse and virtual reality (VR) discourse. AR discourse is a form of communication in which the objects being discussed may be perceptually mediated by the senses. For example, the statement, "*I moved the chair to the other side of the room,*" is an AR statement in that one can perceive the actual objects being moved. In contrast, VR discourse is the form of communication in which the perceptual mediation

is limited if not impossible, and may only be understood through the use of symbols representing the objects being discussed. The statement, "*I moved the  $x$  to the other side of the equal sign,*" is an example of a VR statement. In this case,  $x$ , is a variable, a varying quantity of unknown value. The equal sign is a symbol to denote some type of relationship between two mathematical quantities. Note that in both cases, the symbols of  $x$  and  $=$  refer to abstract mathematical objects that are not immediately perceivable to the human senses. However, in spite of the differences between the symbol/object relationship between AR and VR discourse, note that both types of discourse are structurally similar and use symbols mediated by objects, be they perceived or not (Sfard, 2000). While most of mathematical discourse lies under the category of VR discourse, it is not always the case for geometry.

One major difference between geometry and other areas of mathematics (algebra, arithmetic, or probability) is the perceivable, AR, connection between geometric concepts and actual objects (Doerfler, 1996). From a conceptual standpoint, a triangle, being a 2-dimensional figure, does not have a real word object that represents the defining qualities of a triangle. A triangle in its purest mathematical form is a two-dimensional object having no depth, that is made up of the union of three one-dimensional line segments at their endpoints, each having no thickness. Such an object does not exist in the physical world. However, what does exist is the ability to construct a drawing of a triangle that accurately reflects the essence of the definition. Furthermore this object, for all practical purposes, is a widely agreed upon as the representation of a triangle which allows for the AR discourse of triangles.

Despite the AR nature of geometric figures, there are many relational concepts in geometry that are not immediately perceivable to the senses and are mediated through the process of deduction on known properties and symbols of geometric objects. The statement, "A square is a parallelogram," is a relationship that is traditionally constructed not based on the objects themselves, but rather through a deductive mental process. A parallelogram is a quadrilateral with two sets of parallel sides. A square has two sets of parallel sides, therefore a square is type of parallelogram. This differs from the statement, "A collie is a dog." In this AR statement there are perceivable characteristics, namely that a collie looks like other dogs that allow one to construct a meaningful relationship.

What has changed as result of the advent of dynamic geometric software is a new class of geometric objects that may be manipulated in a manner to allow for AR discourse on traditionally VR concepts. In the program Shape Makers (Battista, 1998), one example is a dynamic on screen object known as a parallelogram maker. This on-screen object may be dragged, turned, and morphed into various forms while preserving the defining qualities of a parallelogram. We use this notion of AR and VR discourse to talk about the ways in which children construct mathematical relationships through perceptual mediation that previous to dynamic geometric software could only be constructed through abstract deductive processes.

Another important concept in this investigation of student discourse in a dynamic geometry environment is Doerfler's (2000) notion of prototypes. These processes involve the perceptive, discursive and cognitive interaction with, and the manipulation of, some kind of mathematical model. This model, known as a concrete carrier, may be an object, a drawing, or a mathematical expression be it physical or imagined. In this case, the carrier is a computerized on-screen representation of geometric objects. It is important to realize that the carrier themselves do not represent the respective concept. For example, a common carrier used in understanding rectangles is a pencil line drawing of a rectangle. The concept of a rectangle that an individual brings to the drawing is restricted to their prototype of a rectangle. To a young child, the prototype may be limited to a number of real life examples. However, to a mathematician, the prototype may allow for the visualization of non-Euclidean representations of rectangles. In this way, the same drawing is a carrier for very different prototypes.

Doerfler (2000) describes three types of prototypes that are applicable to this investigation into student discourse and thinking in a dynamic geometry environment. They are figurative prototypes, operative prototypes, and relational prototypes. In constructing figurative prototypes, the learner's interaction with the concrete carrier leads to a perceptive understanding focusing on the properties, distinctive features and internal relations of the concept. A student's understanding of a square's defining properties, congruent sides and congruent angles, would be considered a figurative prototype for that shape. One powerful feature of a dynamic geometric representation of a square via the square maker is that these figurative prototypes may be developed saliently in that while the square maker is morphed and manipulated, it preserves its defining characteristics. Essentially, a figurative prototype emphasizes the qualities of an object in the foreground, with the operations on the objects in the background.

The second type of prototype, operative, focuses on the operations on the concrete carrier. In geometry, possible operations would be isometric and non-isometric transformations. For example, a shape made with a trapezoid maker may be isometrically translated, rotated or reflected allowing for the visualization of congruent trapezoids in different orientations. These concepts of isometric transformational geometry, which is often illustrated by teachers with paper cut out of shapes that are rotated and flipped on the blackboard or overhead are easily visualized via dynamic geometric representations. A particularly distinctive feature allowed by dynamic geometric representations is the capacity to morph and reshape certain objects to build relationships with other objects. For example, a trapezoid maker can be reshaped to make a figure that is a square. This morphing capability leads us to the last type of prototype, relational.

Relational prototypes refer to the construction of specific relations constructed at the concrete carrier. In a paper and pencil curriculum, unlike figurative and operational prototypes, these relationships are not immediately perceivable, but must be mediated and constructed cognitively. For example, the fact that a square is a parallelogram would represent a relational prototype between a square and parallelogram. Such a
